ACKNOWLEDGMENTS

This study was carried out within the framework of the Research Group on Reservoir Characterization at KFUPM, funded by the Deanship of Scientific Research through Research Group Grant RG-1401.

I would like to express my sincere gratitude to King Fahd University of Petroleum & Minerals and Geosciences Department for giving me this scholarship to study Master of Science in Geology.

I am deeply indebted to my advisor, Prof. Michael Kaminski, and my former advisor, Prof. Ahmet U. Dogan, for knowledge, patience, encouragements, and continually supportive and directive feedback in the process of writing my thesis. Further appreciation goes to Dr. Mohamed A. Morsy for allowing me to utilize the laboratory facilities at Chemistry Department and for the fruitful discussions throughout the research process. I would like also to express my appreciation to Prof. Gabor Korvin, and Dr. Waleed Abdulghani. Many thanks also go to Dr. Dave Cantrell for his valuable comments during the interpretation of the data.

I would specially like to thank Mr. Hatim Dafalla, (Center for Engineering Research – Research Institute, KFUPM) for assistance during analytical work; and Mr. Husam Alzain & Mr. Tarek Akif (Geosciences Department, KFUPM) for assistance in the field.]

ABSTRACT

Full Name : Omar Atef Radwan

Thesis Title : Dedolomitization of Jurassic Tuwaiq Mountain Formation, Riyadh, Saudi Arabia

Major Field : Geology

Date of Degree : December, 2015

Two diagenetic processes (chertification and calcitization) distinguish the Jurassic (late Callovian) upper Tuwaiq Mountain Formation (Daddiyah member) in central Saudi Arabia. Field study, petrography, mineralogical analyses, and geochemical analyses were performed on carbonate and chert samples collected from the Khashm Al-Qaddiyah outcrop to determine the distribution, petrography, cause, and timing of the chertification and calcitization diagenetic processes.

While chertification affected the upper third of the Daddiyah member, the dolomite calcitization process affects the whole member and part of the underlying member. Based on studying the texture (fabric-preserving) and relicts (evaporite) within the cherts, the chertification process was found to affect carbonate and evaporite precursors. The dolomite calcitization process displays a series of cementation, replacement, and dissolution fabrics. The source of silica, forming the microcrystalline quartz of the cherts, is biogenic judging from the abundance of sponge spicules in the chert and upper Tuwaiq Mountain carbonates. Vanished evaporite is suggested to be the driving force for the dolomite calcitization process. Their existence is indicated from the carbonate pseudomorphs after lenticular gypsum and evaporite relicts within the cherts. The paragenetic sequence is interpreted in the following sequence: 1) evaporite precipitation, 2) dolomitization, 3) chertification, 4) evaporite dissolution, 5) Dolomite calcitization.

ملخص الرسالة

الاسم الكامل: عمر عاطف رضوان

عنوان الرسالة: دراسة عملية التكلس في متكون جبل طويق، الرياض، المملكة العربية السعودية

التخصص: جيولوجيا

تاريخ الدرجة العلمية: ديسمبر 2015

يتميز الجزء العلوي من متكون جبال طويق ذو العمر الجوراسي، كما ورد في الدراسات السابقة، بعملية النشأة اللاحقة؛ التكلس (تكوّن الكالسييت عقب الدولوميت) وتكوّن الشيرت. وتهدف هذه الدراسة إلى التوصيف الكامل لعملية التكلس؛ توزيعها، سببها، وتوقيتها. في هذه الدراسة تم استخدام الدراسة الحقلية والمجهريّة والتحليل المعدني والكيميائي لعينات الصخور الجيرية والشيرت في منطقة غرب الرياض بالمملكة العربية السعودية.

تظهر عملية التكلس في عدة أشكال؛ نسيج السمّنة، نسيج الابدال، ونسيج الانحلال. وتتركز هذه الأشكال في الجزء العلوي والأوسط من المتكون. ويُعزى حدوث هذه العملية لنوبان المتبخرات (الصخور الملحية) وتفاعلها مع الدولوميت. ويستدل على التواجد المُسبق للمتبخرات في هذا المتكون من بقايا المتبخرات المتبقية داخل صخر الشيرت في الجزء الأعلى من المتكون. وقد فسر ترتيب عمليات النشأة اللاحقة كالتالي؛ ترسب المتبخرات مصاحبا لتكوّن الصخر الجيري، فالدلمتة، ثم تكوّن الشيرت، ثم نوبان المتبخرات فالتكلس.

CHAPTER 1 | INTRODUCTION

1.1 Dedolomitization

Based on experiments and field studies in Styria, Von Morlot (1847) coined the term ‘dedolomite’ to call the secondary calcite occupying the volume formerly taken by dolomite. Later, ‘dedolomite’ and ‘dedolomitization’ were criticized as terms for being ambiguous, geochemically misleading, and inconsistent with the nomenclature for other types of mineral replacements (Smit and Swett, 1969). Instead, others utilize the terms ‘calcitization’ (Smit and Swett, 1969) or ‘dolomite calcitization’ (Scholle and Ulmer-Scholle, 2003) for being a more logical, meaningful, and acceptable name for the replacement process of calcite-after-dolomite. In this study, the three terms are utilized interchangeably.

Most of the early publications related to dolomite calcitization were released in the 1960s and 1970s (Shearman et al., 1961; Evamy, 1963, 1967; Friedman, 1965; Dickson, 1966; De Groot, 1967; Perkins, 1968; Katz, 1968, 1971; Smit & Swett, 1969; Braun & Friedman, 1970; Al-Hashimi & Hemingway, 1973; Hanshaw & Back, 1979; Plummer & Back, 1980). A significant increase in the number of publications in the field was witnessed in the last decade (Figure 1).

Dolomite calcitization is considered to be; a primary hydrogeochemical processes that dominate groundwater quality (Hanshaw & Back, 1979), a tool for authenticating dolomitic marble sculptures (Margolis, 1989), a driving mechanism for karst generation

([Raines & Dewers, 1997](#)), and an analogue process for assessing the long-term behavior of a CO₂ deep geological storage ([Prado-Pérez & del Villar, 2011](#)). It is also suspected for the degradation of concrete containing dolomite aggregate ([Gillott, 1964](#)). Although porosity changes associated with calcitized dolomite sequences are inconsistent and difficult to predict, they are often characterized by their high porosity which makes them a reservoir for water and hydrocarbons ([Purser, 1985](#)). It is also associated with a number of ore forming processes ([Boni et al., 2011](#)).

Dolomite calcitization has been recognized as an important process in the diagenetic histories of a wide range of Precambrian (e.g. [Kargel et al., 1996](#)) to Phanerozoic (e.g. [Bischoff et al., 1994](#)) marine, lacustrine, and terrestrial carbonates. Understanding the genesis of these carbonates is important in reconstructing the geological history of a region. Many field and experimental studies have supported the conclusion that dedolomitization is a surficial phenomenon (e.g. [De Groot, 1967](#); [Al-Hashimi & Hemingway, 1973](#)), related to post-burial surface weathering and other near-surface processes associated with subaerial exposure, including the development of unconformities and karstic aquifers. Nevertheless, in some cases dedolomitization can take place during deeper burial diagenesis (e.g. [Budai et al., 1984](#)). Calcite does not commonly develop a rhombohedral habit in limestones. Therefore calcite partially or entirely filling rhomb-shaped pore space, or replacing dolomite crystals, constitutes the most straightforward evidence of dolomite calcitization (Figure 2; [Coniglio, 1978](#)).

Numerous challenges face the researchers in the field of dolomite calcitization:

A. Several phenomena have been described as dedolomitization and calcitization.

‘Dedolomitization’ term has also been used as an all-encompassing definition to refer

to any alteration affecting dolomite (Fairbridge, 1978). This alteration includes the dissolution of dolomite without precipitating calcite (Acero et al., 2013). It also includes the dissolution of dolomite with precipitating minerals other than calcite; quartz, gypsum, barite, celestite, (Decrée et al., 2008) kaolinite, iron oxides, and smithsonite (Boni et al., 2013). ‘calcitization’ term is also utilized for other mineral forming process. For instance, calcitization of aragonite grains and cements (e.g. Rabier et al., 2008; Lin et al., 2009; Rogala et al., 2010), calcitization of sulfate minerals (e.g. Stafford et al., 2008; Brasier et al., 2011), and calcitization of silicate minerals (e.g. Hamidi et al., 1998; Giménez-Montsant et al., 1999). About 18% of the studies that uses ‘dedolomitization’ and ‘calcitization’ terms are not related to the topic of ‘dolomite calcitization’.

- B. Dolomite calcitization is a cross-disciplinary field. To fully understand it one has to have a background in thermodynamics, kinetics, geochemistry, and carbonate sedimentology and petrology. It also has applications in many disciplines; petroleum geology, economic geology, hydrology, speleology, archaeology, environmental science, and civil engineering (Figure 3).
- C. Although the term ‘dedolomite’ was introduced by Von Morlot in 1847, 170 years ago, there are still many open questions about the conditions under which calcitization takes place as well as the processes that controls it. The mechanisms and timing involved in the process remain uncertain and are subject of some controversies.
- D. There is no comprehensive studies reviewing different aspects of dedolomitization. There have been several important and valuable reviews dealing with this topic (Chilingar, 1956; Friedman & Sanders, 1967; Coniglio, 1978; Flügel, 2004;

Armenteros, 2010; Braithwaite & Heath, 2013). Most of these studies focused on the identification of the dolomite calcitization process (i.e. dedolomite microfahrics) and one of the mechanisms (i.e. reaction of dolomite with calcium sulfate solutions derived from the dissolution of evaporites). Others focused only on one application (e.g. dedolomitization in concrete).

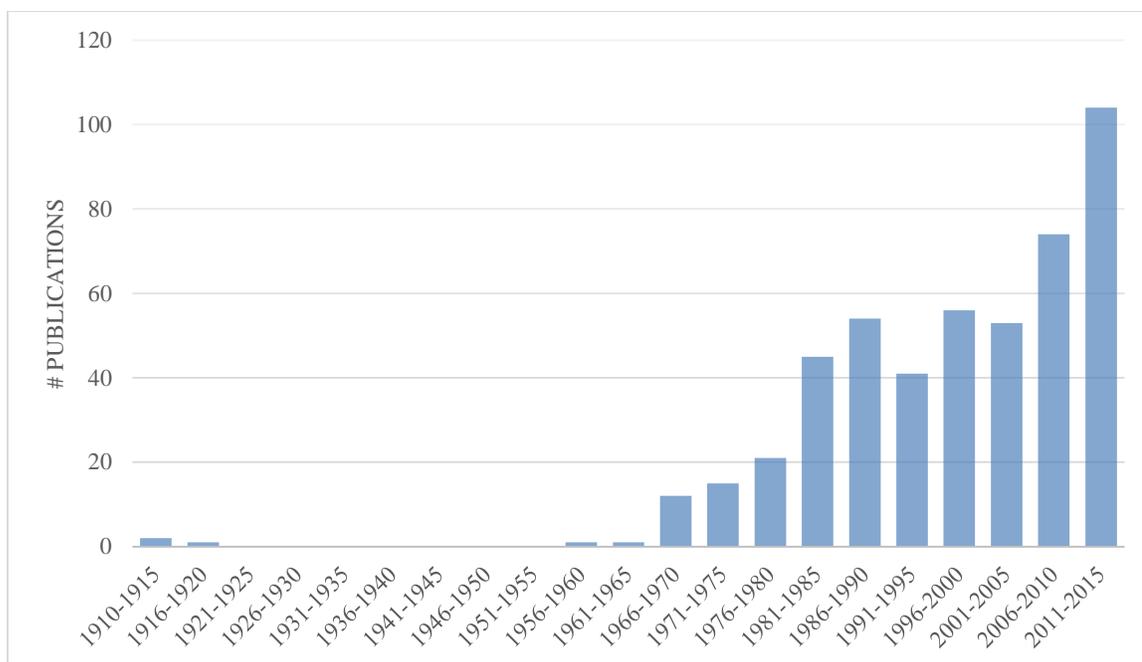

Figure 1. Number of publications in the field of dolomite calcitization increased in the last decade. The data were extracted from the Scopus database using ‘dedolomit*’, ‘calcitization’, or ‘calcitisation’ as key words ([accessed 16 Oct 2015](#)).

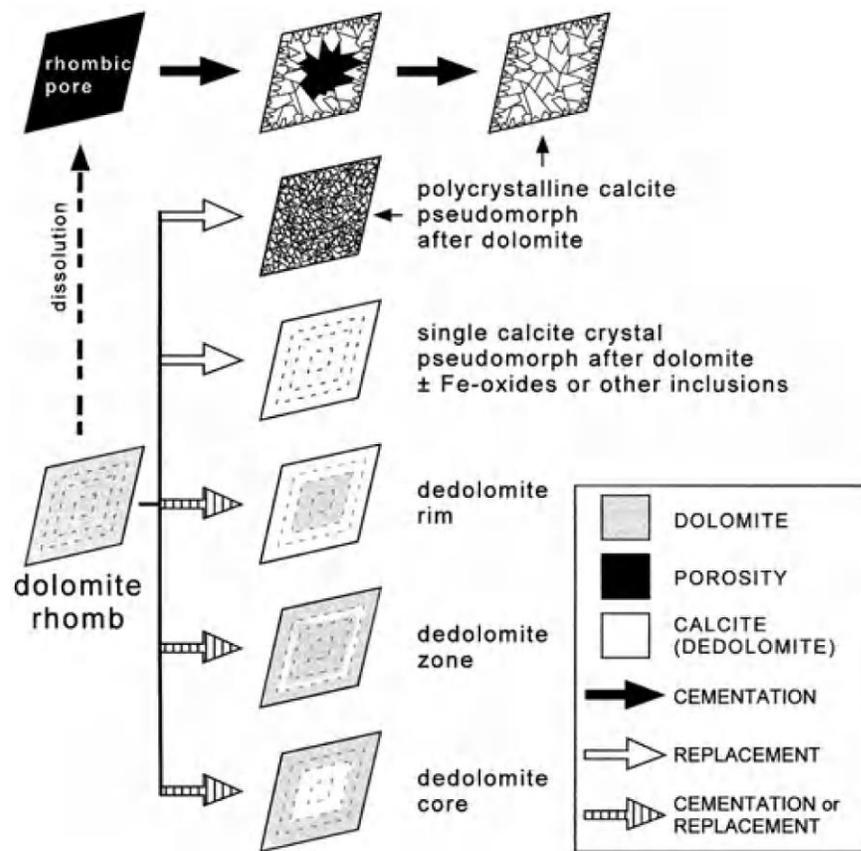

Figure 2. Schematic summary of common dedolomite microfabrics (Coniglio, 1978).

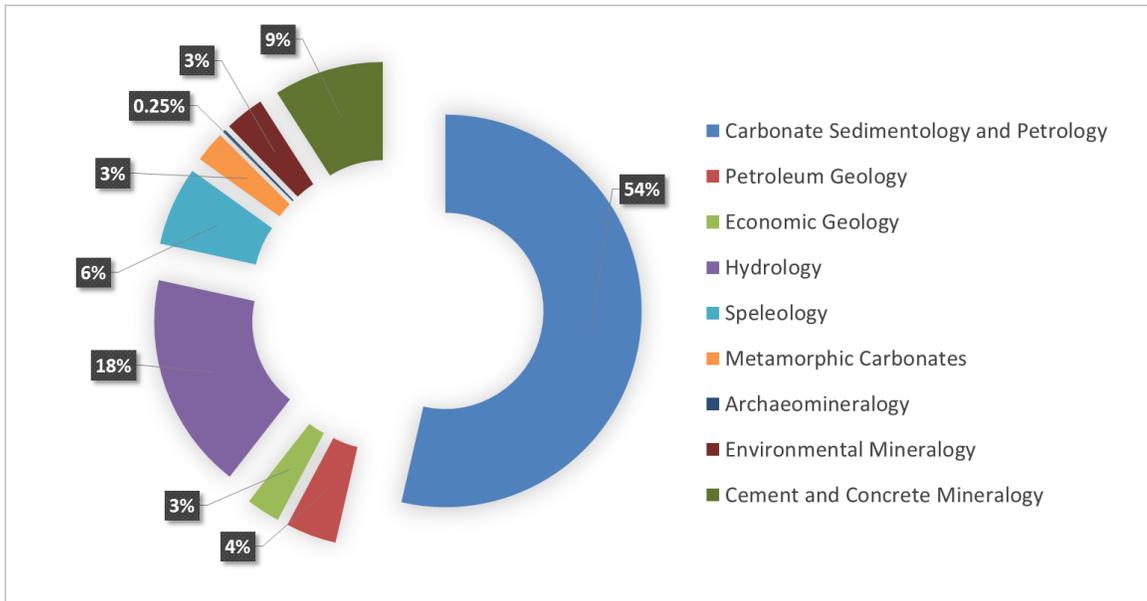

Figure 3. Applications of dolomite calcitization in different disciplines. The data were extracted from the Scopus database using ‘dedolomit*’, ‘calcitization’, or ‘calcitisation’ as key words (accessed 16 Oct 2015).

1.2 Dedolomitization in Saudi Arabia

In Saudi Arabia, dedolomitization was reported in the literature to occur in five formations; Khuff (Khalifa, 2005), Tuwaiq Mountain (Dabbagh, 2006), Jubaila (Cantrell et al., 2007; Basyoni & Khalil, 2013; Eltom et al., 2015), Adgham (Jilh) (Khalifa, 2012), and Usfan (Taj, 2013). Only Jubaila's dedolomitization was studied in detail (Cantrell et al., 2007; Basyoni & Khalil, 2013).

1.3 Tuwaiq Mountain Formation

The Tuwaiq Mountain Formation is a part of the Jurassic Shaqra Group (Mesozoic Dir'iyah supergroup) which includes the Marrat, Dhurma, Tuwaiq Mountain, Hanifa, Jubaila, Arab, and Hith formations (Figure 4: Hughes, 2008). The Tuwaiq Mountain Formation is termed the Sargelu in Kuwait, and the Upper Araej in Qatar and the United Arab Emirates.

The Tuwaiq escarpment represents the major relief feature in central Saudi Arabia. The high-purity limestone of Tuwaiq Mountain enables it to be exploited in many industries; Portland cement, iron metallurgy, paper industry, animal feed stuffs, sewage treatment, and lime manufacture. Parts of the Tuwaiq Mountain are equivalent to subsurface members that host oil reservoirs; Upper Fadhili and Hadriya. Tuwaiq Mountain Formations is considered to be one of the principal source for the oil contained within the southern part of the main producing area of eastern Saudi Arabia.

The Tuwaiq escarpment is the main morphological element in central Saudi Arabia and hence is referred to as the 'backbone of Arabia' (Grainger, 2007). Its height locally

exceeds 200 m and it is found up to 1,000 m above sea level. The escarpment is almost 1,000 km long and extends from the southern margin of the An Nafud in the vicinity of Wadi ArRimah towards the northwestern margin of the Rub'Al Khali, where it is covered by eolian deposits (Figure 5: [Rausch et al., 2014](#)). The main escarpment of Tuwaiq Mountain is composed of the cuesta of the Dhurma (mostly obscured by the debris apron) and Tuwaiq Mountain (which forms the vertical cliff face) formations.

During the Middle to Late Jurassic, the Arabian Peninsula was located in the southern margin of the Tethys Ocean, and was the site of an extensive shallow marine platform (Figure 6: [Al-Husseini, 1997](#)). The period from the Middle Callovian through the end of the Jurassic represents continued deposition in warm equatorial latitudes. This period corresponds to a sustained global sea-level highstand ([Al-Husseini, 1997](#)).

1.4 Literature review

In spite of its importance, the Tuwaiq Mountain Formation is understudied compared to other Jurassic formations (e.g. Arab Formation).

1.4.1 Sedimentological and stratigraphical studies

The Tuwaiq Mountain Formation was formally defined by Bramkamp and Steineke ([Arkell et al., 1952](#)), and was described by [Powers et al. \(1966\)](#) and [Powers \(1968\)](#) who divided it into upper and lower units. Later, BRGM (Bureau de Recherches Géologiques et Minières) group divided the Tuwaiq Mountain Formation into three units T1, T2, and T3 which are informally named Baladiyah, Maysiyah, and Daddiyah members ([Manivit et al., 1985](#); [Vaslet et al., 1988](#); [Vaslet et al., 1991](#); [Énay et al., 2009](#)). Recently, two members

(Hisyan and Atash Members of Dhurma Formation) were added to the Tuwaiq Mountain Formation (Hughes, 2009).

1.4.2 Paleontological and ichnological studies

Many paleontological studies have investigated the Tuwaiq Mountain Formation for its fossil content [Algal microfacies (Okla, 1987), Corals (El-Asa'ad, 1989), Ammonites (El-Asa'ad, 1992), Gastropods (Fischer et al., 2001), Benthic Foraminifera in Coral Reefs (Youssef & El-Sorogy, 2015)]. Micropaleontological characteristics of selected Jurassic unconformities (including Dhurma-Tuwaiq Mountain and Tuwaiq Mountain – Hanifa unconformities) have been discussed by Meyer & Hughes (2000). Hughes (2004, 2008, & 2009) conducted palaeoenvironmental interpretation of the major microfossil and selected macrofossil components of the Shaqra group (Figure 7: Hughes, 2004). El-Hedeny et al. (2012) described and interpreted trace fossils recorded in the formation and determined their environmental significance.

1.4.3 Geomorphological study

Only one study (Rausch et al., 2014) described the distribution of Tuwaiq Escarpment and its different geomorphologic features; gorges, spurs, buttes, and pinnacles.

1.4.4 Diagenetic study

A petrographic study, utilizing polarized microscope, of Jurassic Tuwaiq limestone rocks was conducted by Dabbagh (2006), who reported that lime mudstones and the wackestones constitute the bulk of Tuwaiq Mountain Formation while grainstone is less encountered and floatstone and boundstone are rare. Various diagenetic features were indicated in his study including cementation, micritization, dolomitization,

dedolomitization, and recrystallization. One of the most diagnostic diagenetic features to upper Tuwaiq, i.e. chertification, was not mentioned in this study.

In addition to identifying dolomite calcitization in the Tuwaiq Formation, [Dabbagh \(2006\)](#) described its different characteristic textures and proposed a mechanism of formation. His proposed mechanism was not supported by any evidence.

Discovering the origins and reconstructing the environment that produced any carbonate sequence are challenging tasks. As shown in the literature review, the biological (paleontological and ichnological studies) and physical (sedimentological and stratigraphical studies) aspects have been covered by previous authors. However, the study of the physical and biological factors, if combined with the study of mineralogical and chemical factors can provide a more complete picture of the sedimentary depositional environment. There is a lack of geochemical and mineralogical studies in this formation.

1.5 Objectives

The objectives of this study are listed below;

- 1) To report the distribution of dedolomites in Tuwaiq Mountain Formation.
- 2) To describe the dedolomites' petrographic characteristics.
- 3) To discuss the timing of dedolomitization relative to other diagenetic processes.
- 4) To suggest the source of the calcium-rich solution necessary for the dedolomitization reaction.

1.6 Thesis outline

This thesis consists of five chapters. Chapter one answers the following questions; why did I choose this area of research? Why did I choose Tuwaiq Mountain as a study area? Chapter two answers the following questions; which methods did I utilize in this study? Why did I choose them? How did I use them to get the results? Chapter three answers the following question; what did I find? Chapter four answers the following questions; what do the findings mean? What are the implications of these findings? Chapter five concludes my findings and my interpretation to these findings, and proposes some recommendations for future work.

CHAPTER 2 METHODOLOGY

2.1 Field Work

I have been to the field with my advisor four times [February 22-23, 2015, May 3-4, 2015, August 27-28, 2015, and December 4-5, 2015]. During these field trips we focused on logging the section and collecting samples. We documented our field observations especially those related to diagenesis. We collected representative samples needed for the purpose of my study.

2.1.1 Study area

Because of the difficulty to access the Tuwaiq Mountain Escarpment, we selected a road cut cutting through the formation. The outcrop succession examined in this study (Figures 8, 9) is a roadcut located along the Riyadh-Makkah highway, west of Riyadh [24°31'42.2"N 46°23'41.3"E].

2.1.2 Sampling strategy

Seventy samples (carbonates and cherts) were collected from the studied section. The sampling covered the whole road outcrop (encompassing units T1, T2, & T3) but sampling resolution was increased in the upper part (T3) where the chertification and dolomite calcitization have been reported in the previous studies (e.g. [Vaslet et al., 1991](#); [Dabbagh, 2006](#)). While sampling interval for T1 and T2 was 3 m, it was 2 m for T3. Photos for the whole section and for the position of each sample were taken (Figures 9, 10). To label the samples, I utilized the following labeling system: OAR (represents my name's initials)-15 (represents the year in which the samples were collected)-0X (represents the number of the sample).

Figure 8. Satellite image showing an overview of study area. The study area is located at Khashm al Qaddiyah, west of Riyadh ($24^{\circ}31'42.2''\text{N}$ $46^{\circ}23'41.3''\text{E}$). Image provided from KACST, acquired on 16 October, 2014.

Figure 9. View of the Highway 40 road cut, looking east.

Figure 10. Sample 48's location, from the upper dark grey bed.

2.2 Laboratory Work

Different techniques that have been utilized to analyze the samples will be discussed in this section (Table 1).

2.2.1 Polarized Microscope (PM)

Examination using polarized microscope [Olympus EX51] (Figure 11) was conducted on thin sections injected with blue-dyed epoxy to easily recognize the pore spaces. One half of each thin section was stained with alizarin red-S to differentiate between calcite and dolomite. The study of the thin sections (68 samples) utilizing polarized microscope provides information about carbonate components, porosity types, texture types, and dedolomite presence.

2.2.2 Scanning Electron Microscope - Energy Dispersive X-Ray Spectrometer (SEM-EDS)

Examination using SEM-EDS [JEOL 6610 LV- Oxford X-Max^N Silicon Drift Detector] (Figure 12) was conducted on gold coated one cubic centimeter chips. The study of 25 samples provided information about crystals' habit, dedolomites' texture types, and elemental composition.

2.2.3 Inductively Coupled Plasma-Optical Emission Spectrometer (ICP-OES)

Examination using ICP-OES [SPECTRO CIROS VISION] (Figure 13) was conducted on 15 powdered bulk samples. One gram of the powders were weighed and placed in vials of 20 ml filled with 20 ml (5 %) HNO₃ and left reacting for two hours. ICP-OES was utilized to detect variation in some trace elements (e.g. Na, Fe) with the change in depth.

2.2.4 X-Ray Diffraction (XRD)

Examination using XRD [Rigaku Ultima IV] (Figure 14) was conducted on powdered bulk samples. Identification of the mineral content for 25 samples were conducted utilizing XRD. If there was more than one mineral in the sample, the relative concentration of each mineral was calculated.

2.2.5 Automated Porosimeter-Permeameter (APP)

Measurements of porosity and permeability (Figure 15) were conducted on 25 one-inch core plugs that were cut using the core plug drill machine. Porosity and permeability values were measured using Automated Porosimeter-Permeameter [AP-608].

CHAPTER 3 RESULTS

3.1 Field observations

The Tuwaiq Formation cliff is facing west. The thickness of the Tuwaiq Mountain Formation in the study area is about 180 m. The upper part is thicker than the middle and the lower parts (Figure 9).

The most prominent microfacies in the Tuwaiq Mountain limestone rocks are mudstone, wackestone, and packstone. Grainstone is less frequently encountered, and floatstone and boundstone are rare. The lower and upper part is, however, grainier than the middle part.

While few limestone units of the lower part are partly dolomitized, the middle and upper part contains calcite geodes infilling dissolution cavities (Figure 16). The middle part is characterized, in its upper part, by two dark grey beds (Figure 17). The upper part is characterized by a succession of prograding stromatoporoid bioherms (Figure 18). In the uppermost part, chert nodules occur at three horizons within the light yellow limestones (Figure 19). Horizon C (the lower) is grey colored and exhibits lenticular shape with maximum thickness of 10 cm. Horizon B (the middle) is white colored and exhibits lenticular shape with maximum thickness of 35 cm. Horizon A (the upper) is grey colored and exhibits lenticular shape with maximum thickness of 20 cm. Horizon A consists of many lenses stacked on each other. The density of nodular cherts increases toward the top.

Figure 20 shows simplified stratigraphic section of the Khashm Al-Qaddiyah section. Location of the section in Figure 8.

3.2 Petrography

As expected, lime mudstones and the wackestones constitute the bulk of the Tuwaiq Mountain Formation while grainstone is less frequently encountered. Table 2 shows the Dunham classification of the samples based on the microscopic examination.

There are numerous microfabrics in the samples other than the ten microfabric types listed below, but only the microfabrics that are pertinent to dedolomitization process are discussed here.

3.2.1 Microfabric Type-I: Dolomite crystal

Description: isolated dolomite crystals scattered through muddy lime groundmass (Figure 21).

Distribution: this type of microfabric is concentrated in the lowermost part of the studied section.

3.2.2 Microfabric Type-II: Rhombohedral pores

Description: open rhombohedral pores either without (Figure 22-a) or with (Figure 22-b) calcite relicts around the rim.

Distribution: this type of microfabric is concentrated in the uppermost part of the studied section.

3.2.3 Microfabric Type-III: Single calcite crystal pseudomorph after dolomite [C-I]

Description: In most samples rhombohedral porosity has been destroyed by subsequent calcite cementation. Cementation shows a variety of textures (Figure 23-25). C-I stands for cementation texture number one. In C-I, single calcite rhombohedral crystal is occupying the rhombohedral pore (Figure 23).

Distribution: this type of microfabric is concentrated in the upper part of the studied section.

3.2.4 Microfabric Type-IV: Polycrystalline calcite pseudomorph after dolomite [C-II]

Description: The cementation is mostly polycrystalline (drusy texture). In this type of texture, rhombohedra vary in size from 150 to 200 μm (Figure 24). C-II stands for cementation texture number two.

Distribution: this type of microfabric is concentrated in the uppermost part of the studied section.

3.2.5 Microfabric Type-V: Pore-filling & Fracture-filling [C-III]

Description: cementation also exhibits pore-filling (Figure 25-a) and fracture-filling textures (Figure 25-b). C-III stands for cementation texture number three.

Distribution: this type of microfabric is concentrated in the uppermost part of the studied section.

3.2.6 Microfabric Type-VI: Polycrystalline calcite pseudomorph after dolomite [R]

Description: In other samples the dolomite was replaced by composite calcite rhombohedra (Figure 26). In this type of texture, rhombohedra vary in size from 20 to 50 μm . R stands for replacement texture.

Distribution: this type of microfabric is concentrated in the middle part of the studied section.

3.2.7 Microfabric Type-VII: Calcite pseudomorphs after lenticular gypsum

Description: polycrystalline calcite is filling lenticular molds formerly occupied by gypsum crystals (Figure 27).

Distribution: this type of microfabric is concentrated in the uppermost part of the studied section.

3.2.8 Microfabric Type-VIII: Microcrystalline quartz of chert

Description: microcrystalline quartz constitutes the bulk of the chert horizons and nodules (Figure 28).

Distribution: this type of microfabric is concentrated in the uppermost part of the studied section.

3.2.9 Microfabric Type-IX: Evaporite relicts within microcrystalline quartz of chert

Description: relicts of evaporite minerals were found within microcrystalline quartz of the cherts (Figure 29).

Distribution: this type of microfabric is concentrated in the uppermost part of the studied section.

3.2.10 Microfabric Type-X: Sponge spicules in the cherts and the carbonates

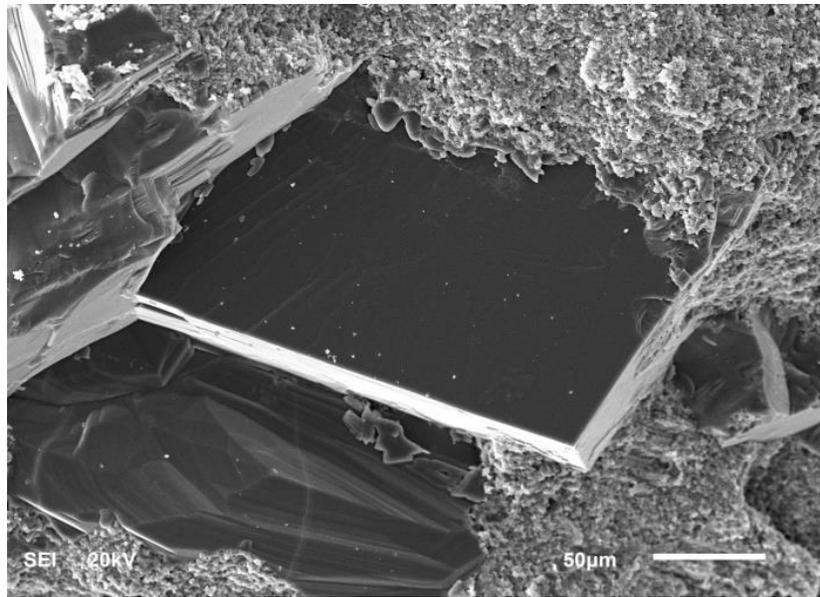

Description: An abundance of sponge spicules in the cherts (Figure 30-a) and surrounding carbonate (Figure 30-b) was observed.

Distribution: this type of microfabric is concentrated in the uppermost part of the studied section.

3.3 Mineralogical composition

Most of the Tuwaiq Mountain carbonate samples (Figure 31) are monomineralic, i.e. formed of pure calcite. The quartz content in the carbonate samples increases in two horizons; around the chert nodules in the upper part (Figure 32-a) and in the dark grey layers in the middle part (Figure 32-b). In the lowermost part, another carbonate phase (dolomite) exists in low concentration. The dolomite concentration increases with depth (Figure 33).

The cherts are composed of microcrystalline quartz. X-ray diffraction analyses show that quartz is the only silica phase present in all samples (Figure 34).

3.4 Chemical composition

ICP-OES was utilized to detect the variation in trace element concentrations in the carbonate samples. There is a significant increase in iron, potassium, and aluminum amount in samples 48 (the dark grey bed). Topmost samples are poor in sodium and iron amount relative to the rest of the formation (Table 3).

3.5 Porosity and permeability

Porosities range from 10-12% in the middle and lower part of the studied section, while the porosity ranges from 5-20% in the upper part. Permeability values range from 0.04-0.3 mD in the middle and lower part of the studied section, while the permeability values range from 0.03-9 mD in the upper part. The wider range of porosity and permeability values of the upper part relative to the middle and lower parts is shown in table 4.

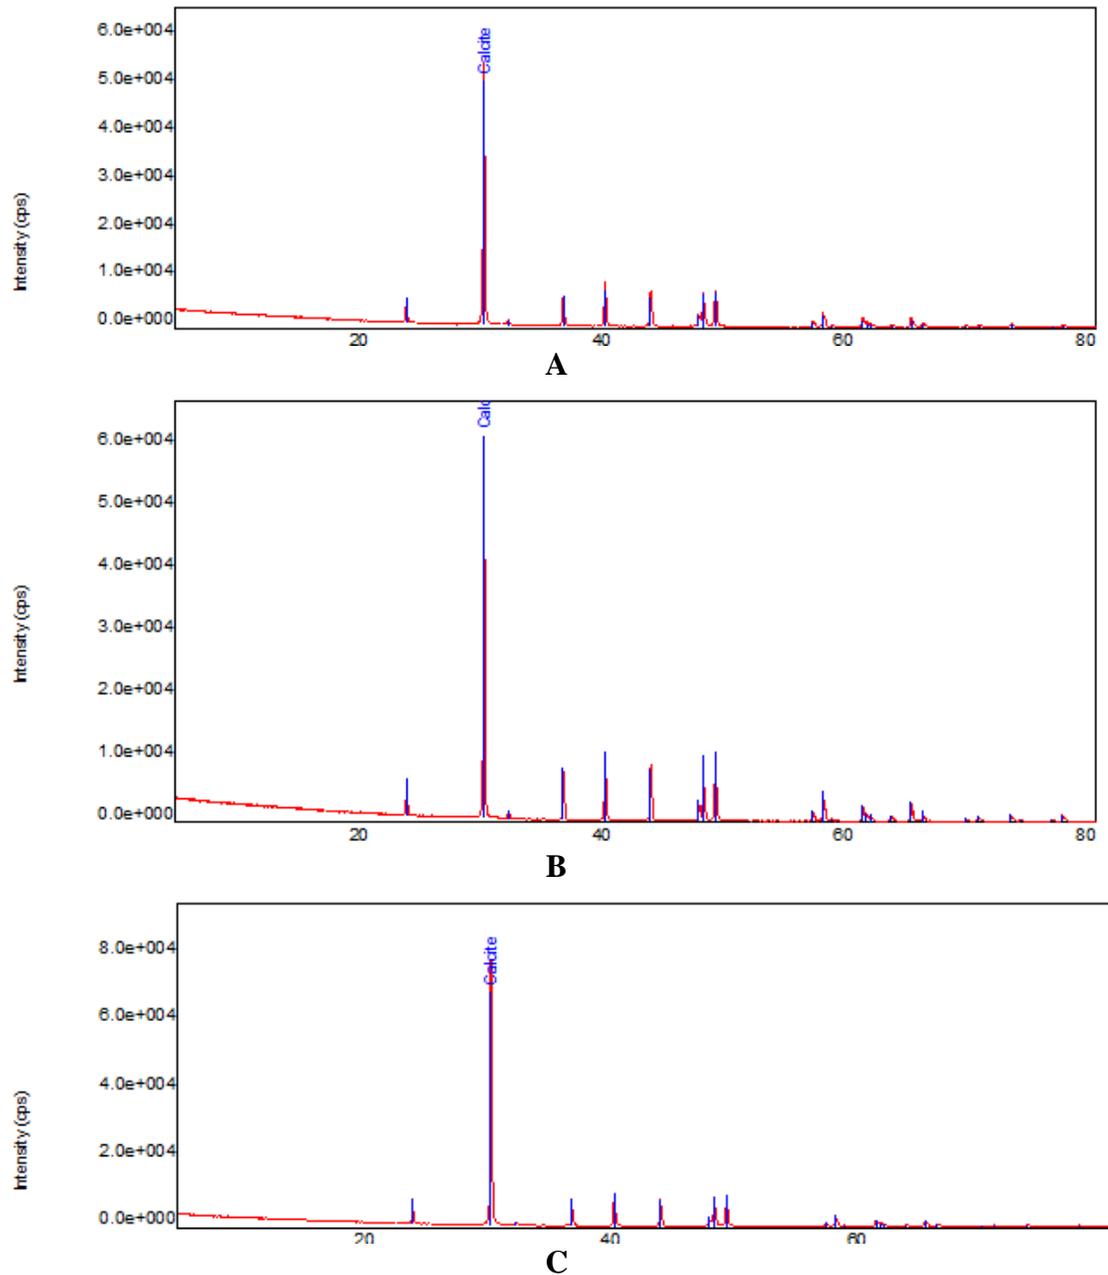

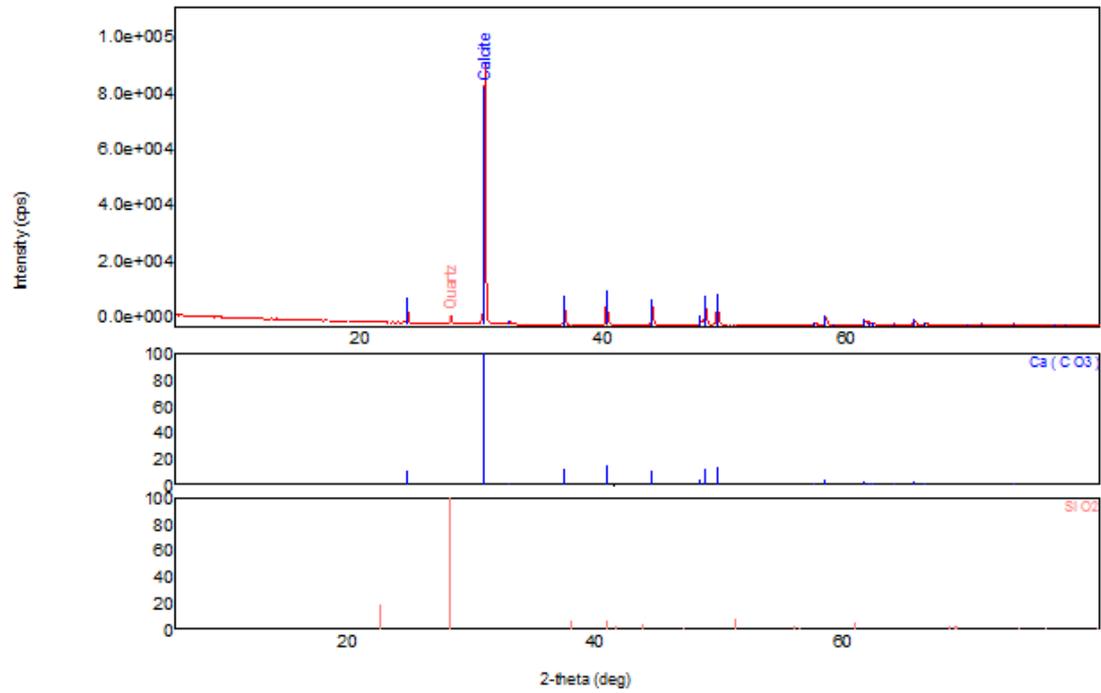

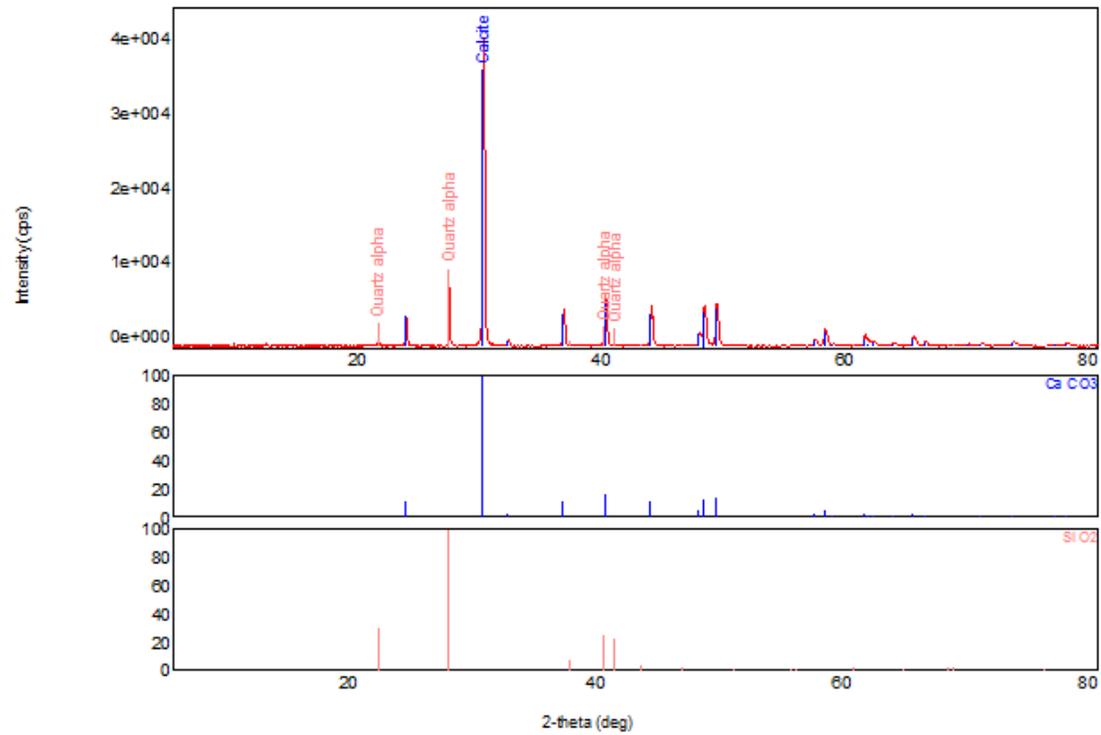

Figure 31. Most of the carbonate samples of the studied area are formed of calcite only. **A)** XRD pattern of sample # 02: 100 % calcite. **B)** XRD pattern of sample # 12: 100 % calcite. **C)** XRD pattern of sample # 22: 100 % calcite.

CHAPTER 4 DISCUSSION

4.1 Chertification

Two mechanisms of chertification are recognized; replacement of carbonate by silica and replacement of evaporite nodules by silica. Cherts are replacing carbonate judging by the fabric-preserving texture of some cherts. Cherts are replacing evaporite precursor judging by relicts found within the cherts (Figure 29).

Hughes (2004 & 2009) considered that chert occurrences in the formation represents silica remobilization of concentrations of sponge spicules deposited during the maximum flooding of parasequences. In my study, the organic origin of silica was confirmed based on the abundance of sponge spicules in the chert (Figure 30-a) and the upper Tuwaiq Mountain carbonate (Figure 30-b).

4.2 Dedolomitization

4.2.1 Dedolomitization Distribution

The lowermost part is not affected by the calcitization process. This is supported by the increase in the dolomite concentration with depth and absence of calcite geodes. Thus, the lowermost part is considered a zone of no filtration of dedolomitizing fluid. On the other hand, the middle and upper parts are affected by the calcitization process. This is supported by the abundance of different textures of rhombohedral calcites and rhombohedral pores. Thus, the dedolomitizing fluid has infiltrated the upper and the middle

parts. The dedolomite microfabrics reflect the behavior and the characteristics of the dedolomitizing fluid (see next section).

4.2.2 Dedolomitization Microfabrics

Calcite does not commonly develop a rhombohedral habit in limestones. Therefore calcite partially or entirely filling rhomb-shaped pore space, or replacing dolomite crystals, constitutes the most straightforward evidence of dolomite calcitization (Coniglio, 1978). Various textures of rhombohedral calcites and rhombohedral pores have been recognized in the middle and upper part of the studied section.

Rhombohedral pores seem to be caused by dolomite dissolution or the selective leaching of mineralogically unstable high-magnesian calcite (Figure 35; Railsback, 1999), believed in many cases to be the initial product of dedolomitization (Evamy, 1967).

Drusy calcite cementation, which is dominant in the upper part, is observed to precipitate in the fractures and pore spaces (intergrains and dolomite molds). Porosity changes in two-step dolomite calcitization are expected depending on which step is dominant; dissolution or precipitation.

Pseudomorphic replacement, which is dominant in the middle part, was governed by the condition of equal volumetric rate for dolomite dissolution and calcite precipitation (one-step dolomite calcitization). No change in porosity is expected to take place where this mechanism of dolomite calcitization occurs. According to Longman (1980) "Meteoric waters have precipitated the excess calcium carbonate picked up in the vadose zone and reached equilibrium with the surrounding sediments by the time they get into the deeper

parts of the freshwater phreatic zone. Thus, little additional cementation occurs. Recrystallization may be an important process, but often occurs within the grains across a narrow front". In case of dedolomitization, the recrystallization occurs through a mechanism called 'coupled dissolution reprecipitation reactions' (CDR) causing the pseudomorphic replacement ([Altree-Williams, 2015](#)).

There are three main differences between calcite precipitated as cement and calcite precipitated as replacement during the dolomite calcitization process. First, calcite precipitated as cement occurs by two-step process (dissolution of dolomite then precipitation of calcite), while during calcite precipitated as replacement the dissolution and precipitation are closely spatially coupled at the interface between the dolomite and calcite. Second, calcite precipitated as cement does not necessarily preserve the external morphology of the parent dolomite (usually corroded), while calcite precipitated as replacement preserves the external morphology of the parent dolomite. Third, calcite precipitated as cement develops single or polycrystalline crystals without intracrystalline porosity and permeability, while calcite precipitated as replacement develops intracrystalline porosity and permeability which allows the fluid to maintain contact with the reaction front.

Numerous authors (e.g. [Folk, 1974](#); [Lahann, 1978](#)) have commented on the diverse morphologies of calcite cements and have attempted to relate crystal morphology to the chemical environment of precipitation. Freshwater calcite cement crystals tend toward equant shapes, while marine calcite and aragonite cement crystals tend toward elongate fibrous shapes (Figure 36; [Folk, 1974 redesigned by Moore & Wade, 2013](#)). Based on the morphologies of the dedolomites, the solution causing the dedolomitization is meteoric.

The microfabrics of the dedolomites indicates different meteoric diagenetic environment (Figure 37; Longman, 1980 redesigned by Hartmann & Beaumont, 1999). The absence of the dedolomites in the lower part indicates that the meteoric solution responsible for the dolomite calcitization did not infiltrate this zone. This is supported by the increase of dolomite concentration and the absence of calcite geodes in the lower part. The middle part of the outcrop contains dedolomites characterized by pseudomorphic replacement texture. This type of texture is caused by meteoric water of stagnant nature (no circulation). This is supported by the similarity of the iron and sodium concentrations between the middle and lower parts. The cementation and solution textures displayed by the dedolomites in the upper part indicate phreatic active zone (causing different cementation textures) and late phreatic zone of solution or late vadose zone of solution (causing the rhombohedral pores texture). This is supported by wider range of porosities in the upper part and the lower concentration of iron and sodium caused by the circulated meteoric water.

4.2.3 Dedolomitization Mechanism

Dabbagh (2006) attributed the calcitization process to the dissolution of massive anhydrite deposits of the Arab and Hith Formations. An alternative explanation is given here based on the new finding of evaporate relicts within the chert nodules. The Jurassic formations consist predominantly of carbonates. Siliciclastics are interbedded within the Toarcian, Bajocian, and Bathonian Marrat and Dhurma formations. Evaporitic sediments become more common in the Kimmeridgian and Tithonian Arab and Hith formations. The lower part of the Tuwaiq Mountain Formation has been described in the literature to be

marly (Manivit et al., 1985; Vaslet et al., 1988; Vaslet et al., 1991). On the other hand, the existence of evaporites has never been reported in the Tuwaiq Mountain Formation.

Two lines of evidence reveal the presence of former evaporite nodules in the upper Tuwaiq Formation; carbonate pseudomorphs after lenticular gypsum (Figure 27) and presence of evaporite relicts within the chert nodules (Figure 29). Therefore, the vanished evaporite nodules are assumed to be the source of the Ca-rich solution necessary for the dolomite calcitization reaction.

4.2.4 Dedolomitization Timing

Partial dolomitization was widespread throughout the formation. The dolomitizing fluids were produced after evaporite precipitation. Then, chertification of organic origin replaced most of the evaporite and the surrounding carbonate. Later, meteoric water dissolved the remaining part of the evaporite causing dolomite calcitization to occur.

Figure 38 summarizes the findings and the interpretations of this study.

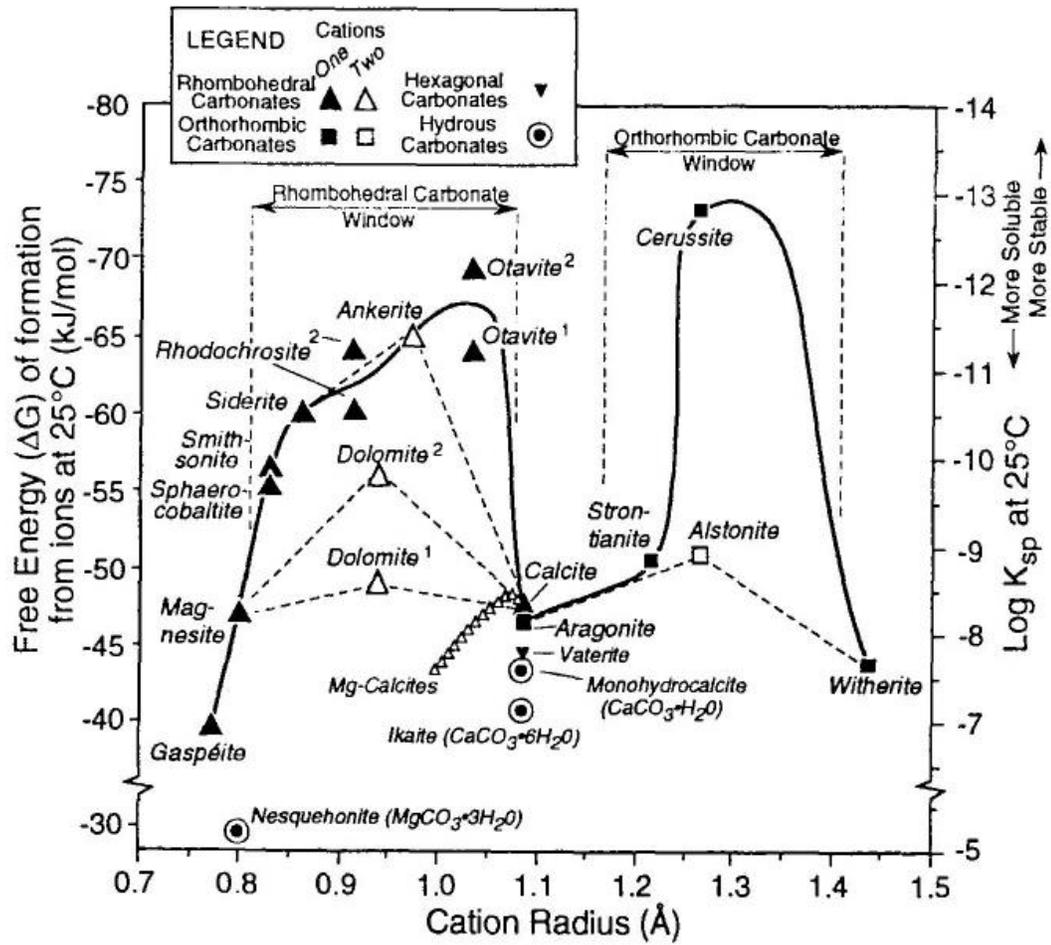

Figure 35. Plot of the free energy of formation from cations (left side) and solubility constants (right side) in rhombohedral carbonates (solid triangles) and orthorhombic carbonates (solid squares) with respect to cationic radius. Minerals higher in diagram are more stable (less soluble) (Railsback, 1999).

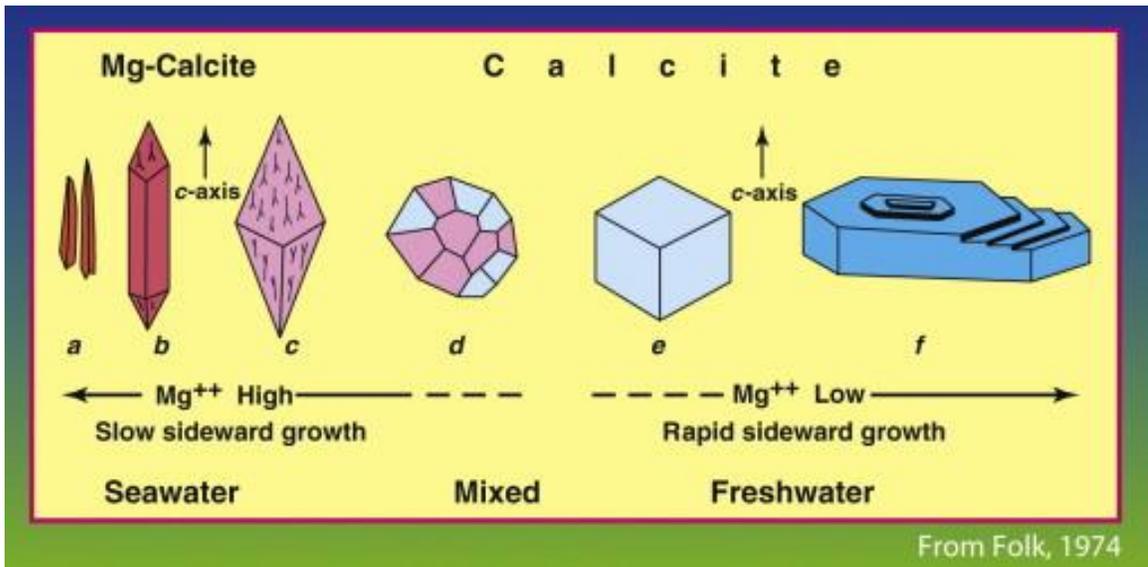

Figure 36. Calcite crystal growth habit as a function of Mg/Ca ratio (Folk, 1974 redesigned by Moore & Wade, 2013).

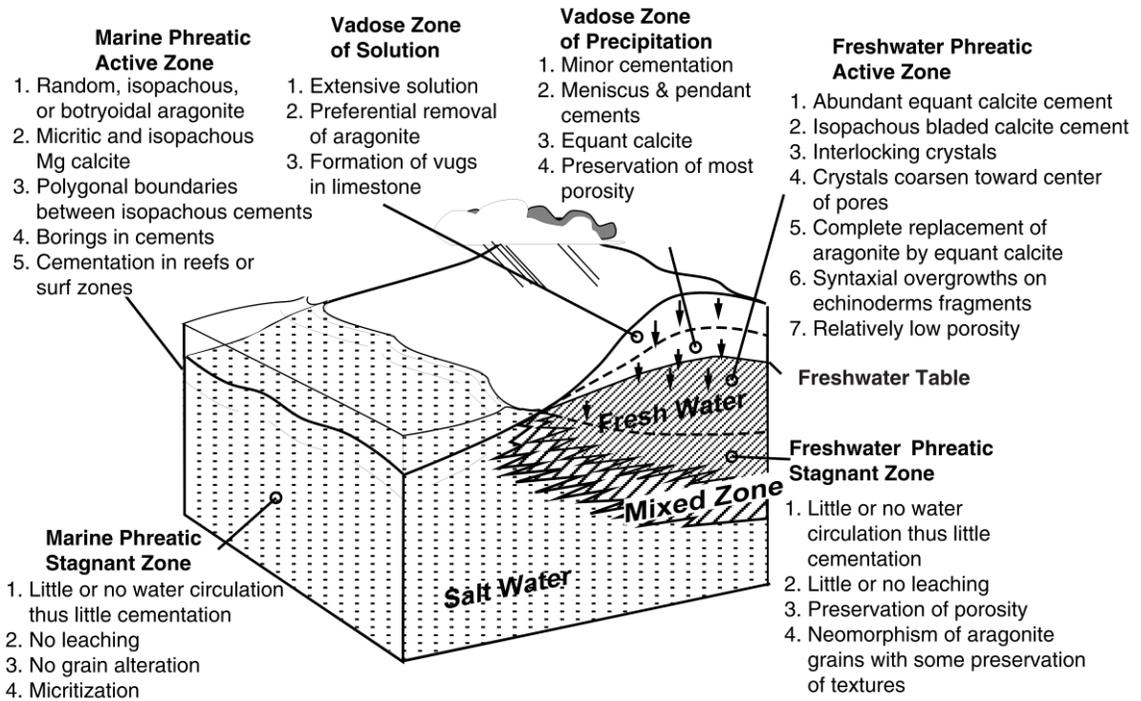

Figure 37. Block diagram summarizes early diagenetic processes and products that occur in carbonate environments (Longman, 1980 redesigned by Hartmann & Beaumont, 1999).

Table 5. Paragenetic sequence of events for Tuwaiq Formation carbonates in the study area. Both the terms 'early' and 'late' diagenesis should be conventionally understood as relative in time, rather than as indicating an absolute age.

Diagenetic sequence	Early	Late
Evaporite precipitation		
Dolomitization		
Silicification		
Evaporite dissolution		
Dolomite calcitization		

My Findings							My Interpretation	
Tuwaiq Zones	Field Observations		Chemistry		Porosity	Minerals	Petrography	Diagenetic Environment
	Chert	Calcite Geodes	Na	Fe	∅		Dedolomite Texture & Distribution	
Upper	Y	Y	1	3	5-20%	Cal+Qz	Cementation and Dissolution Textures	Phreatic Active Zone and Late Phreatic Zone of Solution
	Y		4	5	10-12%		Cementation Textures	Phreatic Active Zone
		Cementation and Replacement Textures					Transitional Zone	
Middle	N				Cal+Qz+Clay	Replacement Texture	Phreatic Stagnant Zone	
Lower		N				Cal+Dol+Clay	No Dedolomitization	No filtration

Figure 38. Summary of the findings and their interpretation.

CHAPTER 5 CONCLUSIONS AND RECOMMENDATIONS

5.1 Conclusions

- Two diagenetic processes (chertification and calcitization) distinguish the Jurassic (late Callovian) upper Tuwaiq Mountain Formation (Daddiyah member).
- While chertification affected the Daddiyah member only, the dolomite calcitization process affects the Daddiyah member and part of the underlying member.
- Strong evidences (evaporite relicts and calcite pseudomorph after gypsum) confirm the former presence of evaporite within the upper Tuwaiq Formation.
- Cherts, of organic origin, are replacing a carbonate and evaporite precursor judging by the fabric-preserving texture and relicts found within the cherts.
- Vanished evaporite is suggested to be the driving force for the dolomite calcitization process. Dissolution of evaporite provides a calcium source necessary for the calcitization reaction to take place.
- Porosity changes appear to be related with the type of dedolomite texture. Replacement fabrics appear to have no effect on the porosity. The cementation fabric seems to decrease the porosity, while the dissolution fabrics increase it.
- The paragenetic sequence is interpreted as follows: 1) evaporite precipitation, 2) dolomitization, 3) chertification, 4) evaporite dissolution, 5) dolomite calcitization.

5.2 Recommendations

- Microsampling for cement would have given more indicative results about the diagenetic environment.
- Analysis of Insoluble residues should be performed on some samples that contain minute amounts of unidentified authigenic minerals.
- The $\delta^{18}\text{O}$ composition of the silica should be checked to confirm if the silica replacing carbonates is distinct from that replacing evaporite. The result of this will indicate if there are two separate sets of conditions for silicification or it is just one phase of replacement.
