## **ACKNOWLEDGMENTS**

All praise to the Almighty for his countless blessings bestowed upon me and giving me the strength to complete this work. Without his help, nothing is possible. No words of thanks are enough to express my gratitude towards him.

I am proud to have been awarded scholarship by King Fahd University of Petroleum & Minerals throughout my Master's program, for which I am extremely thankful to the University.

I am grateful to my thesis advisor, Dr. Abdullah Sultan who allowed me the opportunity to work in my area of interest and mentored and guided me throughout the research. His contribution to this work is immense.

I would like to thank my thesis committee members, Dr. Abu-Khamsin and Dr. Mohamed Kandil for their valuable input and suggestions throughout my work and I am honored to have them in my thesis committee.

I would also like to express my thanks to the Center of Integrative Petroleum Research (CIPR) at The Research Institute (RI) of KFUPM for providing me the funding to conduct my research project and for providing access to conduct experimental work at Fluid Characterization Lab and Multi-purpose core-flood lab. A special acknowledgment to Engr. Abdussamad who helped, facilitated, supported and guided me greatly throughout the research conducted. In addition, Engr. Aziz Khan and Engr. Ali Khalid helped me a lot in core preparation and polishing disks for CA experiments.

I would also like to thank Engr. Zaid Zafar for his continuous help, guidance and support in conducting the IFT experiments and measuring high pressure densities for my thesis. I am thankful to Muzammil Shakeel and Wasef Nofel for providing the oil data. I shall be grateful to Zeeshan Sheikh and Shams Kalam for helping me with ANN techniques.

I also thank all my friends at KFUPM especially Sarmad Zafar Khan and Mobeen Murtaza, who have been my support system during this entire time I spent at KFUPM. Osama Yousef has been a brother to me who provided conveyance every time I needed, Muhammad Mansoor Alam helped me in shopping and I will always be grateful to Muzammil H. Rammay and Danish Hashmat for their unconditional care and immense help. Special thanks to Aneeq Nasir, Owais Ahmad, Ahmad Sadeed and Hassan Sheikh.

## **ABSTRACT (ENGLISH)**

Full Name : Ahmad Mahboob

Thesis Title : Interfacial Tension and Contact Angle Measurements of CO<sub>2</sub>/Brine/Surfactant/Oil Systems with Dolomite Rock

Major Field : Petroleum Engineering

Date of Degree : December,2016

In this work the effects of different parameters such as surfactant type, salinity, temperature, pressure, and oil type have been studied experimentally in the presence of CO<sub>2</sub> at temperatures of up to 90°C and pressures as high as 5500 psi for changes in interfacial tension and wettability with dolomite rock.

EOR techniques are the main source of increase in recovery factor for most wells of today. Surfactants and Water-alternating-gas (WAG) are modern EOR techniques that are more focused and strategic and define a new way of increasing oil recovery. Most of the experimental studies on IFT and Contact angle have been conducted on either Gas (CO<sub>2</sub>)-with-brine or Brine-with-Surfactants. No work has been done previously for measuring interfacial tension and contact angle of CO<sub>2</sub>/Brine/Surfactant/Oil/Dolomite co-existing. If a seawater containing a surfactant is injected into the reservoir followed by CO<sub>2</sub> injection, the former will reduce the interfacial tension of the oil and CO<sub>2</sub> will cause a decrease in viscosity and cause a better displacement of hydrocarbon. Therefore, their combination will cause a relatively high hydrocarbon recovery.

In the 1st step, IFT of four multicomponent brines of different salinities were compared and the brine showing lowest IFT with CO<sub>2</sub> was used in the 2nd step for comparison of three different brine-surfactant solutions (BSS). The BSS with lowest IFT was then used

to study the IFT behavior of three different oils with CO<sub>2</sub>. Last step consists of contact angle (CA) measurements of oil with dolomite rock in the presence of CO<sub>2</sub> and BSS. Brines are multicomponent with salinities ranging from 8,464 to 67,708 ppm. Comparison of surfactants is among solutions of an alcohol-propoxysulfate surfactant, a viscoelastic surfactant and a fluorosurfactant.

IFT of brines increases with increase in salinity and temperature and decreases with increase in pressure. This is due to solubility of CO<sub>2</sub> in brine. IFT increases linearly till density difference of 0.2 g/ml and forms a plateau (or a region of less increase) at certain region of density difference and as the density difference increases further, the IFT slope changes again making it almost linear. The drop volume increases with pressure and decreases with temperature. IFT decreases with increase in pressure for brine-surfactant solutions (BSS) also. Out of the three surfactants, most soluble solution is a fluorosurfactant and gives ultra-low IFT with CO<sub>2</sub>. This BSS of fluorosurfactant when used with oil, forms pressure-sensitive micro emulsions in CO<sub>2</sub> causing the IFT of the oil to decrease. CA of oils with dolomite rock increase with pressure in the presence of fluorosurfactant and CO<sub>2</sub>. Effect of micro-emulsions on CA has also been reported and a correlation has been constructed using ANN that depends on IFT, density and pressure for CA prediction in these systems.

In the literature, comparison of IFTs of different surfactants in CO<sub>2</sub>-Brine systems, Brine-Oil systems, Surfactant-CO<sub>2</sub> systems, and surfactant-oil systems have been reported but this work reports on all CO<sub>2</sub>/Brine/Surfactant/Oil/Dolomite co-existing which can help in planning a Surfactant-Alternating-Gas(SAG) or Water-Alternating-Gas(WAG) process accurately.

تقنيات الاستخلاص المعزز للنفط هي المصدر الرئيسي لزيادة معامل الاستخلاص لمعظم الآبار. تقنيات الاستخلاص المعزز باستخدام خافض التوتر السطحي وعملية تبادل الماء والغاز تعتبر تقنيات حديثة لزيادة استخلاص الزيت. خوافض التوتر السطحي تعمل على إيقاف تشبع الزيت المتبقى وتغيير درجة التبل بهدف زيادة استخلاص الزيت. هناك حالات في عملية تبادل الماء والغاز عندما تتوارد موائع مختلفة من تقنيات الاستخلاص المعزز للنفط مع موائع المكمن. معظم الدراسات العملية على التوتر السطحي وزاوية التماس تم إجراؤها على غاز (ثاني أكسيد الكربون) مع محلول ملحي أو محلول ملحي مع خافض التوتر السطحي. لا يوجد عمل أجري لقياس التوتر السطحي وزاوية التماس لأنظمة ثاني أكسيد الكربون/المحلول الملحي/خافض التوتر السطحي/النفط/صخر الدولومايت.

إذا تم ضخ ماء البحر المحتوي على خافض التوتر السطحي داخل المكمن متبعاً بغاز ثاني أكسيد الكربون، فإن محلول ماء البحر يعمل على إيقاف تشبع التوتر السطحي للزيت، كما أن الغاز يسبب خفضاً للزوجة مما يؤدي إلى أراحة أفضل للهيدروكربون. وبالتالي، اندماج هذه الوائع يسبب استخلاص أفضل للهيدروكربون.

في هذا العمل يتم إجراء دراسة عملية لتأثير عوامل مختلفة مثل نوع خافض التوتر السطحي ودرجة الملوحة ودرجة الحرارة والضغط ونوع الزيت في حضور غاز ثاني أكسيد الكربون على درجة حرارة أكثر من 90 درجة مئوية وضغط عالي عند 5500 بي إس آي، ومدى تغير التوتر السطحي ودرجة التبل مع صخر الدولومايت.

الخطوة الأولى يتم فيها مقارنة التوتر السطحي لأربعة محلائل ملحية مختلفة التكوين ودرجة الملوحة، والمحلول الملحي المحتوي على أقل توتر سطحي مع غاز ثاني أكسيد الكربون يتم استخدامه في الخطوة الثانية ليتم مقارنته مع ثلاثة محلائل ملحية مع خافض التوتر. محلائل الملح مع خافض التوتر ذات التوتر السطحي الأقل تستخدم فيما بعد لدراسة سلوك التوتر السطحي لثلاثة زيوت مختلفة مع غاز ثاني أكسيد الكربون. الخطوة الأخيرة تتكون من قياسات زاوية التماس للزيت مع صخر الدولومايت في حضور ثاني أكسيد الكربون ومحاليل الملح مع خافض التوتر. محلائل الملح عبارة عن مكونات متعددة مع درجات ملوحة تتراوح بين 8464 إلى 67708 جزء بالمليون. مقارنة خوافض التوتر هي بين خافض التوتر (-alcohol) و خافض التوتر (propoxysulfate) وخافض التوتر ذو الزوجة المرنة (fluorosurfactant).

التوتر السطحي للمحاليل الملحية يزيد مع زيادة درجة الملوحة ودرجة الحرارة وينقص مع الزيادة في الضغط. هذا بسبب ذوبانية غاز ثاني أكسيد الكربون في محلول الملح. الترت السطحي يزيد بصورة خطية حتى التغير في الكثافة يصل إلى 0.2 غم/مل، ونقل هذه الزيادة عند حد معين من تغير الكثافة، وعند زيادتها فإن منحنى التوتر السطحي يتغير مجدداً بصورة خطية. من الثلاثة خوافض التوتر، خافض التوتر الأكثر ذوبانية هو (fluorosurfactant) ويعطي توتراً سطحياً مع غاز ثاني أكسيد الكربون بقيمة قليلة جداً. محلول الملح وخافض التوتر هذا يستخدم لاحقاً مع الزيت لتكوين مستحلب دقيق يتاثر بالضغط مع غاز ثاني أكسيد الكربون، مسبباً إيقاف التوتر السطحي للزيت.

في الكتابات العلمية، مقارنة التوتر السطحي لخوافض التوتر المنخفضة في أنظمة ثاني أكسيد الكربون/المحلول الملحي، وأنظمة محلول الملحي/الزيت، وأنظمة خافض التوتر/ثاني أكسيد الكربون، وأنظمة خافض التوتر/الزيت قد أشير إليها،

ولكن هذا العمل يشير إلى ثاني أكسيد الكربون والمحلول الملحي وخافض التوتر والزيت وصخر الولومايت كلها مجتمعة. هذا العمل قد يساعد في التخطيط لعمليات تبادل خافض التوتر والغاز أو تبادل الماء والغاز بصورة دقيقة.

# **CHAPTER 1**

## **INTRODUCTION**

### **1.1 Introduction to EOR and Interfacial phenomenon**

Enhanced Oil recovery (EOR) is used to increase oil recovery from oil reservoirs beyond their natural production capability. One of the famous EOR processes is CO<sub>2</sub> injection which is being used as a tertiary EOR in more than 70 operations in USA [1]. The main reason for successful development of this process is the availability of low cost CO<sub>2</sub>.

#### **1.1.1 CO<sub>2</sub> EOR:**

Injection of CO<sub>2</sub> at supercritical pressure to displace the immobile oil to producing zone can also serve as a means of reducing the amount of CO<sub>2</sub> in the atmosphere by capturing and sequestering in the mature reservoirs. CO<sub>2</sub> has been closely linked to global climate change hence there are incentives to sequester it. It is a good solvent for light crudes as well as miscible with oil at moderate reservoir pressures. The number of projects injecting CO<sub>2</sub> has been steadily rising and anticipated to increase further in the foreseeable future. CO<sub>2</sub> can easily be in a supercritical fluid state at relatively low temperature and pressure conditions. From phase diagram, Figure 8, critical point of CO<sub>2</sub> is at 1070 psi and 32°C.

Application of CO<sub>2</sub> flooding as means of enhanced recovery has its challenges which various investigators have tried to solve over the decades. The common challenges being

faced are gravity segregation, reservoir heterogeneity and high mobility ratio of CO<sub>2</sub> [2]. These cause a reduction in macroscopic sweep efficiency even though the microscopic efficiency sweep efficiency may be high.

### **1.1.2 Water-Alternating-Gas (WAG):**

The WAG process, patented by Parrish in 1966, was initially proposed as a method to increase the sweep efficiency during gas injection. In WAG processes, water and gas are injected as alternate slugs either in cycles or simultaneously in order to improve the sweep efficiency of waterflooding and miscible/immiscible gas flood. Because of their low viscosities, miscible gases generally have poor flood performance than water does in a waterflood. Almost all-commercial miscible floods today employ the WAG method. In addition to improving sweep efficiency, WAG injection was found to improve the displacement efficiency in heavy oil reservoirs by oil phase swelling and viscosity reduction [3]. This oil phase swelling is governed by capillary pressure reduction.

### **1.1.3 Surfactant Alternating Gas (SAG):**

An improved form of WAG process is Surfactant-Alternating-Gas (SAG) in which a surfactant solution is injected alternating with CO<sub>2</sub> or N<sub>2</sub>. Surfactant serves the purpose of generating foam with CO<sub>2</sub> which helps in further reduction of CO<sub>2</sub> mobility and improves CO<sub>2</sub> displacement efficiency as reported in both field and laboratory studies by several investigators [4]–[9].

There are many carbonate reservoirs in US below their minimum miscibility pressure that are naturally fractured [10]. For water wet formations, waterflooding is very effective but many fractured carbonate reservoirs are mixed wet and recoveries with conventional

methods are low (less than 10%). Thermal and miscible tertiary recovery techniques are not effective in these reservoirs[10]. Therefore use of surfactants for flooding is the only hope [11], although in the past it was developed for sandstone reservoirs [12].

SAG provides higher oil recovery because foam has better viscosity and also increases the trapped gas saturation. The first observation of trapped gas influence on residual oil saturation was reported by Holmgren and Morse (1951). Trapped gas has been found to lower residual oil in several experimental studies [13]. Another benefit is the cost. For SAG process, 85 to 95% of gas is used and therefore saves water consumption as compared to WAG [2]. Surfactant also serves to decrease the interfacial tension of the fluids.

Surfactants (surface active agents) are compounds whose molecular structures contain both hydrophobic (water repelling)/lipophobicity (lipid/fat/oil repelling) and hydrophilic/CO<sub>2</sub>-philic (water or CO<sub>2</sub> attracting) groups. Most surfactants consist of a hydrophobic tail group and a hydrophilic head group. When added to an aqueous fluid, surfactant molecules combine to form structures known as “micelles”. Surfactants reduce IFT and aid in the solubilization of hydrophilic compounds into hydrophobic solvents or vice versa due to their amphiphilic nature [14]. The hydrophilic heads surrounds the core that is formed by association of hydrophobic tails of the micelles. This isolates the tails from contact with water. Micelles are typically spherical in shape.

In this work supercritical CO<sub>2</sub> will be used that has a major drawback. It is a poor solvent because of extremely low polarizability/volume ratio and many lipophilic and hydrophilic

compounds are not soluble. In order to render CO<sub>2</sub> a better solvent for these compounds, surfactants are necessary.

The interfacial tension,  $\gamma$ , of CO<sub>2</sub> with mixtures representative of the fluids in underground formations is an important thermophysical property for the design of SAG EOR process. It has been long recognized that interfacial interactions (interfacial tension, wettability, capillarity and interfacial mass transfer) govern fluid distribution and behavior in porous media. This work focuses on interfacial tension and wettability measurements.

#### **1.1.4 Interfacial Tension:**

The interfacial tension (IFT) is the free energy per unit surface area that is required for creating an interface between two condensed phases. The IFT is an important factor in a number of applications related to surfactant injection for improved oil recovery, emulsion stability, transport of organic contaminants through soil, and ensuring water quality in aquifers, which includes the ability to predict the behavior of dense nonaqueous phase liquids such as chlorinated solvents. The IFT influences the capillary pressure between two nonmiscible fluids, which in turn impacts how fluids flow in porous media. Other applications where IFT plays a major role include micelle formation and other self-assembly processes of nanoparticles or colloidal particles at liquid/liquid interfaces. Self-assembly at liquid/liquid interfaces is an important process in materials science and technology, which is highly relevant to food supplements and cosmetics. The IFT also plays an important role in pharmaceutical applications such as drug delivery, where surfactants help to form microemulsions, which improves the bioavailability of lipophilic

or amphiphilic drugs [15]. Lowest interfacial tension is always desireable since low IFT corresponds to high mobility and stable foam [2].

### **1.1.5 Wettability:**

Wetting phenomenon plays an important role in our everyday lives. The behavior and properties of materials such as paints, adhesives, detergents, and lubricants are all manifestations of wetting phenomena. Furthermore, wetting is an essential element in the behavior of biological systems. For examples, studies of wetting properties of plant leaves has helped to develop insecticides that repel insects and protect the leaves from diseases. Investigation of cell adhesion to biological membrane, and the tear film which wets the eyeball facilitating vision are other phenomenon studied because of wetting phenomenon. Very often contact angle studies are used to gain insight into the fundamentals of wetting many systems. Contact angle is defined as the angle between the tangents to the planes of two intersecting interfaces at their intersecting line; of the two possible angles according to the convention, contact angle is the angle measured through the denser phase. Although it seems conceptually easy to measure contact angles for many systems, contact angle phenomena are by no means a simple subject matter. Contact angle depends on many factors such as heterogeneity of the system, presence of surfactants, smoothness of the surface, line tension [16], density and the size of the drop. All of these factors need to be understood to better understand and predict the wettability of a fluid. However studying all of the participating factors at once can be very complex; the present thesis will focus on the contact angle get better understandings of the subject. The interfacial formation wettability is considered as one of the controlling parameters

for residual oil recovery from carbonate reservoirs. It has a significant impact on relative permeability, capillary pressures and on oil displacement in porous media [17].

In either cases of co-injection of Surfactant solution and gas or surfactant alternating gas, the CO<sub>2</sub>, water, oil and surfactant will co-exist in the reservoir. In the current literature, separate systems have been used by several authors, mentioned in Chapter 2, such as CO<sub>2</sub> with Water/Brine, CO<sub>2</sub> with surfactants, Surfactants with Oil, and CO<sub>2</sub> with Oil. There has been a gap in literature for co-existance of IFT data for CO<sub>2</sub>, Brine, Oil and Surfactant. Also not a lot of work has been done on dolomite rock with Oil and CO<sub>2</sub> systems.

## **1.2 Problem Statement and Thesis Objectives:**

Current understanding of the interfacial properties for reservoir when there is a coexistence of EOR fluids in the reservoir needs to be revised because of the following reasons:

- 1- There is a need to study methods for decrease is IFT and wettability for SAG injection
- 2- Current literature does not cover the combinations of CO<sub>2</sub>, brine, Oil and surfactants co-existing.
- 3- Florosurfactant with CO<sub>2</sub> and oil has not been used before.
- 4- Very less work has been done on Contact Angle with carbonate rocks especially high purity dolomite.

Owning the above shortcomings, the main objective of the thesis are as follows:

- i- Study the interfacial properties of CO<sub>2</sub>, Brines containing surfactants and oil coexisting.
  - ii- Study the effect of:
    - a. Change in brine salinity
    - b. Change in temperature
    - c. Change in pressure
    - d. Type of surfactant
    - e. Type of oil (model oil and crude oil)
- on interfacial properties (Interfacial tension and wettability) of the various combination of systems.

# **CHAPTER 2**

## **LITERATURE REVIEW**

Main focus of this work is interfacial tension and contact angle measurements of CO<sub>2</sub>, Brine, Oil and Surfactant systems. This chapter covers all the studies that have already been published related to these systems.

### **2.1 Interfacial Tension Measurements**

Bachu and Bennion (2009) studied the effect of pressure, temperature and brine salinities on interfacial tension of CO<sub>2</sub> – water [18]. They performed 378 IFT measurements between CO<sub>2</sub> and water/brine at 20 to 125 °C temperatures and for pressures from 2 to 27 MPa. Five multi-component brines with salinities ranging from 0 to 334 010 mg·L<sup>-1</sup> were used. The laboratory experiments were conducted using the pendant drop method for the profile of the brine drop in the CO<sub>2</sub>-brine equilibrium environment. They showed that at constant salinity and temperature, IFT decreases steeply with increasing pressure when pressure is less than critical pressure and mildly decreases when pressure is greater than critical pressure with an asymptotic trend toward a constant value at high pressures. If the temperature and pressure are kept constant, IFT increases with increasing salinity, which means CO<sub>2</sub> solubility in brine decreases with increase in salinity. For temperature, less than critical temperature, IFT increases with increasing temperature, and close to the critical point ( $T \approx T_c$ ), IFT significantly decreases, probably because at  $T_c$  the IFT between CO<sub>2</sub> liquid and vapor phases tends to zero, and then increases again with

increasing temperature for temperature greater than  $T_c$  with an asymptotic trend toward a constant value for higher temperatures. The dependence of IFT on salinity, pressure and temperature for CO<sub>2</sub>-water/brine systems can be, according to the author, approximated by a power function of pressure whose coefficient and exponent depend on salinity and temperature.

Saraji et al. (2014) in their study used axisymmetric drop shape analysis (ADSA) and no-Apex (ADSA-NA) method to measure density, IFTs, contact angles of CO<sub>2</sub>/brine/quartz systems at high pressures and temperatures [19]. Measurements were performed at 50°C to 100°C temperature and 2000 to 4000 psig pressures and brine salinities from 0.2 to 5 gm/L which is relevant to carbon sequestration in deep saline aquifers. The effect of SO<sub>2</sub> as a co-contaminant was also investigated in this work. Contact angle hysteresis and its implications of the results on some mechanisms of CO<sub>2</sub> trapping was examined. Density of the brine increased with temperature but it remained unaffected by pressure. However density of supercritical CO<sub>2</sub> increased with increasing pressure and decreased with increasing temperature. Variations in pressure did not have a significant effect on the IFT of between equilibrated CO<sub>2</sub>-rich and aqueous phases, but temperature increase caused slight reduction of the IFT. The relative insensitivity of IFT to P and T in the supercritical region of CO<sub>2</sub> may stem from the fact that the solubility of CO<sub>2</sub> in brine does not drastically change in the P and T ranges studied in this work. Similar to the IFT data, the dynamic contact angles also did not change significantly with P and T. There was only a slight increase in the contact angles and contact angle hysteresis by the increase in pressure. However, due to the lack of enough temperature overlap in the presented data, a general trend cannot be deducted. The density of CO<sub>2</sub> was insensitive to the changes in

salt concentration, however brines with the higher ionic strength had larger densities. There was a significant increase in IFT by an increase in the ionic strength. For example, IFT between equilibrated sc- CO<sub>2</sub> and brine at 3000 psig and 60°C increased from 26 to 39 mN/m by changing the ionic strength from 0.2 to 5 M. According to the authors, this behavior was partly due to the decrease in CO<sub>2</sub> solubility in brine at higher salinities and partly because of hydration of ions that leads to an ion-free layer at the water interface.

Kim and Santamarina (2014) studied the manipulation of Capillary factor to attain improved sweep efficiency [20]. It was found through experimentation that surfactants that have hydrophilic heads and CO<sub>2</sub>-philic tails lower the IFT between CO<sub>2</sub> and water. The long- chain nonionic surfactant used in these experiments (weight percent wt.  $\approx$  0.4%) lowered the CO<sub>2</sub>-water interfacial tension from  $\gamma_{fl} \sim 50$  mN/m to  $\gamma_{fl} \sim 4$  mN/m at a pressure of  $P \geq 7$  MPa. The parallelism in surface tension-vs-pressure trends for tests conducted with and without surfactant suggests a pressure-independent concentration of surfactants at the interface. The contact angle formed by a water-surfactant droplet resting on a glass substrate and surrounded by CO<sub>2</sub> increases from  $\theta \sim 20^\circ$  at  $P = 0.1$  MPa to  $\theta \sim 70^\circ$  at  $P = 10$  MPa. Reduced interfacial tension  $\gamma_{fl}$  and larger contact angle  $\theta$  combine to produce a marked decrease in the capillary factor  $\gamma_{fl} \cos \theta$ .

Iglauer et al. (2014) studied contact angle and wettability measurement on a quartz surface after applying different cleaning methods and demonstrated clearly that the main factor which leads to a broad data in different researches is due to surface contamination [21]. It is clear that typically inappropriate cleaning methods were used which resulted in artificially high contact angle measurements. Cleaning methods described in surface

chemistry community were used and it was found that the water contact angle  $\theta$  on a clean quartz substrate is low, 0–30°, and that  $\theta$  increases with pressure. They concluded that quartz is strongly water-wet at high pressure conditions.

Chalbaud et al., (2010) performed interfacial tension and contact angle experiments using ADSA technique between CO<sub>2</sub> and brine at conditions of geological storage [22]. Experiments were performed at 4.5 MPa to 25.5 MPa and at temperatures 27, 71 and 100°C and for single component (NaCl) brine with salinity ranging from 5000 to 150 000 ppm. Based on the results authors developed a correlation using the Parachor model, using the sensitivity of salinity and applying a regression fit of more than one hundred IFT experimental values.

$$\gamma_{b,CO_2} = \gamma_{W_{plateau}} + \lambda * x_{NaCl} + \left[ \frac{P}{M} (\Delta\rho) \right]^\eta * T_r^\beta$$

where  $\lambda$ ,  $\beta$  and  $\eta$  are regression coefficients. Remaining parameters have been explained in the paper. Also in this paper, Glass micromodels were used to study the fluid distribution in the case of different thermodynamic conditions and wettability.

Lun et al. (2012) used axisymmetric drop shape analysis (ADSA) for the pendant drop case to measure IFT between CO<sub>2</sub> and reservoir brine at high temperatures and pressures [23]. Measurements were taken for multi-component brines of three salinities (0 mg/L, 14224.2 mg/L and 21460.6 mg/L) at pressures till 35 MPa and at two temperatures 45°C and 97.53°C. It was found that the equilibrium IFT decreases as the pressure increases but increases as the salinity increases. Also, the wettability of the reservoir brine and CO<sub>2</sub>

system changes from the hydrophilic case to the hydrophobic case as the pressure increases, and the same phenomenon decreases as the brine salinity increases.

Shariat et al (2012) used pendant drop method to measure interfacial tension between CO<sub>2</sub> and water between 7 MPa to 124 MPa and on temperatures up to 204°C [24]. They also measured water-vapor-saturated CO<sub>2</sub> as well as CO<sub>2</sub>- saturated-water densities at each pressure and temperature. They showed that IFT of CO<sub>2</sub> and Water decrease with increasing temperature however quite independent of pressure with values between 10 to 23 dynes/cm. Complete miscibility between CO<sub>2</sub> and H<sub>2</sub>O at any pressure and temperature was never observed. CO<sub>2</sub>-saturated water densities showed a strong dependence on pressure and temperature, while water-vapor-saturated CO<sub>2</sub> densities showed little change from the CO<sub>2</sub> density with no vapor content.

Georgiadis et al. (2011) used pendant drop method, at high pressure and temperature, to evaluate the interfacial tension between water and [(1 - x)n-decane + x CO<sub>2</sub>] for three different compositions of CO<sub>2</sub> in the alkane-rich phase, of mole fractions x = (0.0, 0.2, and 0.5), along several isotherms at temperatures up to 170°C and pressures ranging from the miscibility state points for (n-decane + CO<sub>2</sub>) up to 50 MPa. Bulk phase was [n-decane + CO<sub>2</sub>] and drop phase was water [25]. On comparison with literature, the results of binary system were in complete agreement at ambient pressure whereas for high pressures, the literature values were lower than the work of this study. It was found that IFT of the system (H<sub>2</sub>O + [n-decane + CO<sub>2</sub>] ) system decreases by increasing concentration of CO<sub>2</sub>. Also n-alkane and CO<sub>2</sub> become miscible at high temperatures and pressure and the IFT curve vanishes. The reported results have a relative average standard deviation of 1.7 %.

Sun and Chen (2005) used pendant drop method to study IFT between CO<sub>2</sub> injected crude oil and reservoir water at 66°C and 11.7 MPa [26]. This study was conducted to observe the effect of CO<sub>2</sub> molar composition ( $x_{CO_2}$ ) on the IFT of CO<sub>2</sub> injected crude oil and reservoir water (salinity 2695.58 ppm, Multi-component brine).  $x_{CO_2}$  was ranging from (0, 10.0, 34.1, 44.7, 48.9, 57.8, to 65.0) mol %. The bubble point pressure for these CO<sub>2</sub> injected oil systems was also determined using a PVT device. The experimental data showed that when  $x_{CO_2}$  changed from (0 to 65.0) mol %, the interfacial tension value decreased by about one-third. The pressure had a slight effect on the interfacial tension. When  $x_{CO_2}$  was 65.0 mol %, the CO<sub>2</sub> injected oil system approached complete miscibility and the interfacial tension data of CO<sub>2</sub> injected crude oil with reservoir water changed a little with an increase of pressure.

Yang et al. (2005) used ADSA pendant drop technique to measure IFTs of CO<sub>2</sub> with Brine, Brine with Crude Oil, CO<sub>2</sub> with Crude oil and Crude Oil with CO<sub>2</sub>-saturated-brine at pressures ranging from 0.1 MPa to 31.4 MPa and at two temperatures 27°C and 58°C [27]. For both systems the IFT decreases with increase in pressure and increases with increase in pressure. For CO<sub>2</sub>-Brine systems, at pressure higher than 12.238 MPa at 58°C, the drop was not formed therefore the data is not available. However, for CO<sub>2</sub>-Crude oil system, the IFT remains unaffected at pressures higher than 8.879 MPa at 27°C and 13.362 MPa at 58°C. For Crude oil with Brine systems, IFT is independent of both pressure and temperature. Also IFTs of Crude Oil, CO<sub>2</sub>, and reservoir brine were measured by bubbling CO<sub>2</sub> in the cell containing brine and generating a drop of oil in the CO<sub>2</sub>-saturated-brine. IFT slightly decreased with increase in both pressure and temperature.

Xing et al. (2013) presented a review on the research progress of the interfacial tension in supercritical CO<sub>2</sub>-water/ oil system [28]. He found that according to many researchers that IFT decreases with increasing pressure for both CO<sub>2</sub>-reservoir and CO<sub>2</sub>-crude oil systems. For CO<sub>2</sub>-water system, the quasi-static pendant drop method was utilized to measure IFT at temperatures ranging from 278 to 335 K and pressures from 0.1 to 20 MPa, the IFT showed a pronounced dependence on pressure and temperature. Furthermore for the Crude oil-brine system and the CO<sub>2</sub>+crude oil+ reservoir brine system the IFT remain almost constant at different pressures, but the IFT of the latter is slightly lower at higher pressure because more CO<sub>2</sub> dissolves in the brine and oil phases. So CO<sub>2</sub> injection can be successfully used to enhance oil recovery by decreasing the IFT of reservoir fluid and water, reservoir fluid and CO<sub>2</sub>. For the effect of temperature, different studies have provided different observations therefore the author thinks the effect of temperature of IFT is complex and must be taken into account in future studies.

Gibeau et al. (1986) conducted a series of IFT measurements versus temperature at constant pressure using the pendant drop apparatus with seven different samples of viscous crude oil using as the aqueous phases a source water for water injection, distilled water and heavy water [29]. The temperatures ranged from ambient to 160°C. It was found that for three out of five heavy oil, there was a decrease in IFT with an increase in temperature. It was also concluded that pendant drop technique cannot be used to measure the interfacial tensions when the density difference between the two fluids is less than 0.01 g/cm<sup>3</sup>.

Talebian et al. (2014) studied the interactions of fluids involved in foam assisted CO<sub>2</sub> EOR process at pressure of 7 MPa to 20 MPa, and temperature of 102°C [30]. The

equilibrium CO<sub>2</sub> solubility into the reservoir brine, and crude oil, and the effect of foaming agent surfactants on the CO<sub>2</sub> solubility into the aqueous phase were measured by using an equilibrium high pressure cell. The IFT measurements of gas-liquid and liquid-liquid systems were measured by ADSA pendant drop tensiometer. It was found that the CO<sub>2</sub>-surfactant solution IFT values can also influence the equilibrium solubility of CO<sub>2</sub> in surfactant solution. The lower the IFT at the CO<sub>2</sub>-surfactant interface would result in higher solubility of CO<sub>2</sub> in the solution. CO<sub>2</sub> dissolution in different solvents is dependent on the equilibrium pressure, and temperature. By increasing the pressure, CO<sub>2</sub> dissolution in both aqueous and oil systems increased. By increasing the pressure from atmospheric to 20 MPa, the IFT values decreased significantly from near 20 to 1 mN/m values.

Li et al. (2012a) in their first paper, studied the interfacial tension of different brines (salt molalities of 1 to 5 mol/kg) of (0.864 NaCl+ 0.136 KCl) with CO<sub>2</sub> at temperatures between 298 and 448 K (24°C and 175°C) and pressures between 2 and 50 MPa (290 psi to 7,252 psi) by using pendant drop method, generating a drop of CO<sub>2</sub>-saturated brine surrounded by water-saturated CO<sub>2</sub> phase [31]. The expanded uncertainties at 95 % confidence are 0.05 K in temperature, 70 kPa in pressure, and for interfacial tension  $\gamma$ , the larger of 0.016 $\gamma$  and 0.6 mN·m<sup>-1</sup>. The results of the study indicate that the interfacial tension increases linearly with the molality of the salt solution. An empirical equation has been developed to represent the present results as a function of temperature, pressure, and molality with an expanded uncertainty of 1.6 mN·m<sup>-1</sup>.

Li et al. (2012b) in another paper reported the interfacial tensions between CO<sub>2</sub> and different brines (CaCl<sub>2(aq)</sub>, MgCl<sub>2(aq)</sub>, and Na<sub>2</sub>SO<sub>4(aq)</sub>) each with molalities from (0.49 to 5.0) mol·kg<sup>-1</sup> at temperatures between 343 and 423 K (70°C to 150°C), pressures

between 2 and 50 MPa (290 and 7,252 psi) [32]. The pendant-drop method was implemented in a high-pressure view cell filled with water-saturated CO<sub>2</sub> into which single drops of brine were injected through a suitable capillary. The expanded uncertainties at 95 % confidence are 0.05 K in temperature and 70 KPa in pressure. For the interfacial tension, the expanded relative uncertainty at 95 % confidence was 1.6 %. The results of this study show that interfacial tension increases linearly with molality. Further, it was concluded that at constant temperature and pressure, the interfacial tension is the same function of the positive charge molality for all salts investigated in this work.

Kashefi (2012) made a model on measurement of Interfacial tension between gas-water systems by generating data by performing experiments and using points generated by previous experiments done by several authors [33]. Not only data points from hydrocarbon gases were included, but also from CO<sub>2</sub>, H<sub>2</sub>S and N<sub>2</sub> were used to make IFT-solubility correlation to predict the IFT of gas-water systems. He observed that addition of salt increases the interfacial tension. Also he found that at each temperature, the effect of pressure on the IFT of each system decreases by increasing pressure. For all gases in water, IFT decreases with increase in gas solubility in water.

Cao and Gu (2013) in part of their work measured CO<sub>2</sub> solubility in crude oil and equilibrium IFTs of crude and CO<sub>2</sub> at pressures from 250 psi to 2770 psi and constant temperature 53°C [34]. They found that up till 1200 psi, IFT tends to decrease rapidly with pressure and the cause of this decrease was the increased solubility of CO<sub>2</sub> in the original light crude oil. However, from 1200 up till 2770, the decrease in IFT was less, almost constant. The reason was that, lighter components of the crude oil get dissolved in the CO<sub>2</sub>, and thereby leaving intermediate to heavy components in the crude oil and

therefore the IFT being measured was of the left-over components of the crude oil. He also observed that at low pressures, the pendant oil drop swells due to CO<sub>2</sub> dissolution into the oil phase. It was also observed that CO<sub>2</sub> solubility in the crude oil decreases as the temperature increases in a PVT cell for temperature increase from 27°C to 53°C. As the CO<sub>2</sub> changes into supercritical stage, the extraction ability of light hydrocarbons by CO<sub>2</sub> becomes stronger. However higher recovery is achieved in the second pressure range, i.e. when CO<sub>2</sub> is immiscible and also high temperature is desired for higher recovery in case of CO<sub>2</sub> flooding.

Yang et al. (2015) measured the IFT of CO<sub>2</sub> with two Crude oils and n-hexadecane at up till 140°C and 5500 psi [35]. According to their study, the higher is temperature, the higher is the IFT. IFT tends to decrease with pressure, however there comes a certain threshold pressure 1100 psi at which the IFT stops decreasing and becomes constant (or slightly decrease) with pressure up till 3350 psi. Crude oil A (heavier) decreases rapidly till 1750 psi, whereas crude oil B (lighter) decreases rapidly till 1450 psi. Slight decrease of crude oil A has been reported till 4000 psi whereas for crude oil B till 5500 psi at 60°C. At lower temperature 45°C, crude oil A decreases rapidly till 1300 and slightly till 2175 psi whereas for crude oil B the two pressures are 1450 psi and 2465 psi. The reason for decrease in IFT with pressure can be explained by explaining what is happening at the molecular level. The intermolecular forces operating within the crude oil (dipole-dipole and Debye Force) are much stronger than the ones operating in CO<sub>2</sub> molecules (London dispersion force). Increase in pressure at constant temperature causes the molecular distances to decrease but the intermolecular forces increase. The forces in CO<sub>2</sub> become close (in value) to those in Oil since there is a drastic change in CO<sub>2</sub> molecular distance.

With these molecular forces become higher, IFT tends to decrease. Increase in temperature causes an increase in IFT is also explained by increase in molecular distances. When IFTs of all three fluids are compared, the highest IFT is shown by the lighter crude oil B and lowest is shown by n-hexadecane. According to the explanation in this work, the crude oil's IFT can be compared with each other due to same intermolecular forces. However, n-hexadecane molecules are almost linear with no-polarity therefore only London forces exist therefore the difference in intermolecular forces between CO<sub>2</sub> and hexadecane is smaller than those between crude oils. This is the reason for low-IFT of n-hexadecane. For n-hexadecane drop, higher the pressure smaller is the drop size and smaller is the IFT.

Awari-yusuf (2013) in his thesis measured the interfacial tension between CO<sub>2</sub> and crude oil at 22°C and 60°C and at pressures from 100 to 600 psi [36]. IFT decreases with increase in temperature and increase in pressure. He obtained a straight line for decrease in pressure that can be extended to zero IFT. This point of zero IFT is called minimum miscibility pressure (MMP). At high pressure, MMP reaches earlier at lower pressure. At the end, the author recommends that more data points need to be added to increase the accuracy and also he did not investigate the effect of gas density on IFT.

Akutsu et al. (2007) measured IFT between CO<sub>2</sub> and water in the presence of surfactants [37]. The surfactants used in this work are CO<sub>2</sub>-Soluble hydrocarbon surfactants of three different ethylene oxide (EO) chains were used in this work. Both CO<sub>2</sub> and water-surfactant solutions were saturated with each other and interfacial tensions were measured for different surfactant concentrations. The surfactant concentration with longest EO chains showed the lowest IFT. Reason can be that EO chains are hydrophilic

and longer EO chains have strong attractive force for water surface. The EO chains penetrate into a water droplet when a surfynol molecule adsorbs on water/CO<sub>2</sub> interface. The IFT decreases with increasing surfactant concentration. However at a certain point all IFT values approach a same value indicating the adsorption of water droplet surface by excess amount of surfynol molecules whose hydrophobic tails are interacting with CO<sub>2</sub> molecules. Also the comparison at different temperatures and pressures was shown by the authors on which the fluid densities are same. It showed that IFT decreases with increase in surfactant concentration but at a point reaches a plateau.

Yang et al. (2005) in another paper measured IFT between CO<sub>2</sub> and brine at two temperatures (27°C and 58°C) and nine pressures from ambient pressure to 4351 psi [38]. Brine consists mainly of sodium chloride and bicarbonates and CO<sub>2</sub> is 99% pure. Brine and CO<sub>2</sub> were not in pre-equilibrium in the experiments. It was also observed that Brine drop initially swells and its volume continues to increase at the same pressure with time which is due to CO<sub>2</sub> dissolution in brine phase. After some time it shrinks because of the pendant brine drop mass transfer with CO<sub>2</sub>. At high temperature, the solubility of CO<sub>2</sub> (drop shrinkage) increases. Thus higher the temperature the greater is the amount of brine transfer to CO<sub>2</sub> phase. Also they reported the solubility of CO<sub>2</sub> in brine. It was observed through PVT also that solubility increases with increase in temperature. Also for IFT, at higher temperature brine drop stays for shorter time because CO<sub>2</sub> solubility in the brine phase is lower at higher temperature. At temperature of 58°C and pressure 1775 psi no interface was formed and therefore it was considered that both CO<sub>2</sub> and brine are miscible with each other. Generally, IFT decreases with increase in pressure however IFT increases with increase in temperature because CO<sub>2</sub> solubility in brine phase is higher at

high pressure and low at high temperature, also, the pressure effect on IFT is comparable with temperature effect for the brine-CO<sub>2</sub> system.

Rocha et al. (1999) measured interfacial tension between CO<sub>2</sub> and water in the presence of different surfactants [39]. According to their work, CO<sub>2</sub> is a poor solvent for lipophilic and hydrophilic solutes because of low dielectric constant and polarizability per volume. It is possible to disperse either lipophilic or hydrophilic phases into CO<sub>2</sub> with surfactants. Surfactants with low surface tensions/cohesive densities are highly soluble in CO<sub>2</sub>. Log of IFT when plotted against temperature or pressure, decreases till a point of lowest IFT (at this point the system is balanced with respect to partitioning of the surfactant between the phases) and then increases. This increase is due to migration of the surfactant towards the other phase. Also pressure and temperature can cause change in solvent strength because of the change in density. An example is that water in propane micro emulsion was inverted to a propane in water micro emulsion by varying the pressure by 725 psi. This system undergoes a phase inversion density by analogy with the phase inversion temperature for conventional system. If the density is changed so that the surfactant prefers either phase over the other the surfactant is less interfacially active and IFT increases.

In their work, the drop is of water saturated with CO<sub>2</sub>, whereas the bulk phase contains CO<sub>2</sub> and surfactant. The aqueous phase density was assumed to change less than 0.0025 g/cm<sup>3</sup> because of the presence of surfactants. For one of the surfactants the effect of temperature was examined and it was found that both equilibrium, and minimum IFT decreases with temperature. The reason is that the interactions are strengthened due to increase in density at low temperature which favor the solvation of surfactant.

Emulsification of the water caused turbidity and the amount of water was increased to check the check the amount of emulsification by each surfactant. And high emulsification of water also corresponds with low IFT. Turbidity decreases with time. For two surfactants which produced the same amount of lowering of IFT, the one on the CO<sub>2</sub>-philic side of the v-shaped plot emulsified more water according to Bancroft rule. A distribution coefficient is defined as the ratio of surfactant solubility in CO<sub>2</sub> at a particular temperature and pressure to that of water at 1 atm (14.7 psi). When this coefficient is less than 1, it means the natural curvature for those surfactants would favor CO<sub>2</sub>-in-water droplet according to Bancroft Rule.

Ruckenstein (1996) validated and extended the Bancroft Rule which is stated as “a hydrophile colloid will tend to make water the dispersing phase while a hydrophobe colloid will tend to make water a dispersed phase” [40]. He stated that according to Binks [41], for surfactant concentrations greater than the critical micro-emulsion concentration at which a micro emulsion forms, the macro emulsion type is that of the corresponding microemulsion and that the Bancroft rule holds. However, for surfactant concentrations small compared to the critical micro emulsion concentration, the emulsions formed were of the O/W type and the Bancroft rule was violated, since the higher concentration of surfactant was in the oil phase, hence in the dispersed and not the continuous phase. Emulsions are formed by applying shear that creates oil fingers in water and water fingers in oil at the interfaces of which molecules of the surfactant are absorbed. The stability of an emulsion also depends upon adsorption-desorption process. And the type of emulsion formed depends on mixing process of the fluids. The validation/validation of Bancroft rule in this paper was based on two ratios, one ratio compared the interaction between

surfactant-oil to those between surfactant-water. The other ratio compared between hydrocarbon chains of the surfactant molecules of the interfacial layer and oil to those between the head groups of surfactant layers of IFT and water. When both are smaller or large than unity, Bancroft rule is obeyed.

## 2.2 Contact Angle Measurements

Ameri et al. (2013) determined contact angle using pendant drop shape analysis in systems with CO<sub>2</sub>, brine, and an oil-saturated rock system [42]. Two situations were considered: Rock system I was partially water-wet, whereas rock system II is effectively oil-wet. Contact angles have been determined experimentally as a function of brine salinity and pressure. The experiments were carried out at a constant temperature of 45°C and pressures varying between 0.1 up to 16.0 MPa. For rock system I, the partially water-wet substrate, brine and CO<sub>2</sub> system, the dependence on the pressure at constant salinity is very small. For this system, at a constant pressure, the contact angle decreases for increasing brine salinity. The results show that the carbon dioxide is the non-wetting phase in the pressure and salinity range studied. This behavior can be quantitatively understood in terms of the expected dependencies of the three interfacial tensions (IFTs) in Young's equation on pressure and brine salinity. For rock system II, the effectively oil-wet substrate, brine, and CO<sub>2</sub> system, the dependency of contact angle on pressure is considerable. This study proves that CO<sub>2</sub> becomes the wetting phase at pressures higher than 10.0 MPa. Beyond 10.0 MPa (i.e., in the supercritical region), the contact angle remains practically constant. The effect of salinity on the contact angle of the oil-wet rock system II is small. The behavior can again be quantitatively understood based on

expected trends of the three IFTs that determine the contact angle. It is also shown that use of the equation of state method makes it possible to approach the experimental data quantitatively. It was concluded that contact angle measurements form an essential ingredient to determine the efficiency of carbon dioxide flooding and storage.

Hamouda and Gomari (2006) performed a set of experiments to measure the effect of temperature on contact angle of carbonate rock samples [43]. Saturated, unsaturated fatty acids and naphthenic acids with saturated and unsaturated rings were selected for this work to alter the water-wet calcite surface over a temperature range of 25 to 130°C.

Three approaches were followed by Hamouda and Gomari. In the first approach (test 1), a water pre-wetted calcite surface was modified by aging for 24 hours in a 0.01M stearic acid (SA) dissolved in n-decane at different temperatures. The second approach, the pre-wetted calcite surface was modified by aging for 24 hours in a 0.01M stearic acid dissolved in n-decane at room temperature (25°C) and then immersed in water having the pre-determined temperatures. In the third approach, a water pre-wetted calcite surface was modified by aging for 24 hours in a 0.01 M stearic acid dissolved in n-decane at different temperatures as test 1, then the modified calcite at desired temperature immersed in water having the same pre-determined temperature. In these three approaches the modified calcite after treatment was dried in the air over night and contact angle was measured inside the cell at 25°C.

It was observed that a steeper change in the contact angles for test 1 and 3 than that for test 2. When the temperature increased from 25 to 130°C, the contact angle decreased from 160 to 68° and 160 to 101° for test 1 and 2, respectively. In test 3, where the contact

angles were measured on the modified calcite at the desired temperature followed by immersion in water at the same temperature, lower values than that for test 1 were observed. The lower contact angle observed in test 3 (decreased from 160 to 36° with temperature increase from 25 to 130°C, respectively) compared to test 1 may be explained to be caused by possible re-establishing equilibrium between the adsorbed SA / calcium stearate and water and/or desorption of SA from the calcite surface. The lower contact angles in test 1 and 3 than measured in test 2, may in general, be explained based on the available Ca<sup>2+</sup> sites on the calcite surface. As the temperature increases a lesser Ca<sup>2+</sup> are available for adsorption, the previously reported chemisorption of the SA, on the calcite surface<sup>5</sup>. While in test 2, the strongly adsorbed SA at low temperature, showed lesser degree of alteration of the wettability to water-wet as the temperature increases. This hypothesis was successfully quantified and verified with a simulation of solubility of calcite in an open system (presence of CO<sub>2</sub>) was performed.

Gupta and Mohanty (2008) studied the effect of salinity, surfactant concentration, electrolyte concentration, and temperature on the wettability alteration and identified underlying mechanisms [44]. Contact angles, phase behavior, and interfacial tensions were measured with two oil (one model oil and one field oil). Most of the experiments are done with a model oil which is prepared by adding 1.5 wt. % of cyclohexanepentanoic acid to n-decane. The acid (98 % active) and n-decane were supplied by Sigma-Aldrich. It is called the model oil in this paper. The other oil used was from a West Texas fractured carbonate reservoir. It had 28.20° API, 23.8 cp viscosity (at 27°C), 0.2 acid number and 1.17 base number. Na<sub>2</sub>CO<sub>3</sub> and NaCl were used to change salinity of the aqueous phase. Na<sub>2</sub>SO<sub>4</sub>, CaCl<sub>2</sub>.2H<sub>2</sub>O and MgCl<sub>2</sub>.6H<sub>2</sub>O used to vary

divalent ion concentration in brine were. Calcite (Iceland spar) plates used for wettability experiments. It was found that there exists an optimal surfactant concentration for varying salinity and an optimal salinity for varying surfactant concentration at which the wettability alteration is the maximum for anionic surfactants. Concentration of surfactants in the interface region can explain the occurrence of optimal salinity for wettability alteration. As the reservoir salinity increases, the surfactant concentration needed for the maximum wettability alteration decreases, but the extent of wettability alteration itself decreases. IFT and contact angle were found to have the same optimal salinity for a given concentration of anionic surfactants. Also, IFT was found to be decreasing (and in some cases reaching a plateau value) for increasing surfactant concentrations at a fixed salinity. As the ethoxylation increases in anionic surfactants, the extent of wettability alteration increases. Wettability of carbonates can be altered by divalent ions at high temperature (90°C and above).

Sulfate ions alter wettability to a greater extent in the presence of magnesium and calcium ions than in the absence. A high concentration of calcium ions can alter wettability alone. Magnesium ions alone did not change calcite plate wettability.

Alotaibi et al. (2010) conducted extensive wettability studies to determine the optimum brine salinity which results in higher oil recovery [45]. Crude oil, formation core samples (dolomite, and calcite), and synthetic brines from Middle East (formation, aquifer, and seawater) are used to evaluate wettability quantitatively, and qualitatively. All experiments were conducted at high pressure (up to 2,000 psia), and elevated temperature (up to 270°F).

Hielmeland and Larrondo (1986) [46] studied the effect of pressure, temperature, and oil composition on the wettability of calcium carbonate rocks. Temperature was found to have a large effect on the wetting characteristics. At low temperatures ( $22^{\circ}\text{C}$ ), the solid phase exhibited oil-wet behavior, whereas at high temperatures ( $\geq 60^{\circ}\text{C}$ ), it exhibited water-wet behavior. At  $40^{\circ}\text{C}$  an intermediate state of wettability seemed to prevail. No pressure effect was found on wettability. The wettability of calcium carbonate, on the other hand, was not affected by the light fraction of the oil. Advancing and receding equilibrium contact angles were obtained within 100 to 200 hours.

Saudi Arabian carbonate reservoir wettability was evaluated and compared by Lichaa et al. (1992) using USBM, Amott, and contact angle techniques [47]. Calcite, marble, and formation rocks were used in the receding contact angle measurements, as well as synthetic formation brine, seawater, and dead crude oil. A wide temperature range was examined in all experiments between 25 to  $90^{\circ}\text{C}$ . Test pressure was varied from ambient to 50 psi. Calcite surface tests became preferentially more water-wet at higher temperatures. Contact angle results for oil/brine/marble system was slightly oil-wet to an intermediate wettability, and tended to become weakly water-wet at higher temperatures. Formation rock tests, on the other hand, showed an intermediate wettability or preferentially, slightly oil-wet at room temperature and became preferentially less oil-wet at higher temperatures.

The effect of salinity on the contact angle was investigated by Almehaideb et al. (2004) [48]. Limestone rock, crude oil, NaCl solutions were all used in their study. Four runs were examined using distilled water, 1,000, 10,000, and 50,000 ppm. All experiments

were conducted at room temperature. A significant reduction of oil/water contact angle was observed at 10,000 ppm.

Yang et al. (2008) presented the wettability of the crude oil–reservoir brine–reservoir rock system at elevated temperatures, using the axisymmetric drop shape analysis (ADSA) technique [49]. Vuggy limestone rocks were used in this study with intermediate wettability. The contact angle increased as pressure increased. Slight fluctuation was reported in the contact angle measurement at pressure and temperature of 29 psi and 27°C, respectively. This contact angle fluctuation may be ascribed to be strong electrostatic interactions between the crude oil and the reservoir brine. The contact angle also decreased as increasing the fluid temperature.

Shojaei et al. (2012) studied the wetting behavior of CO<sub>2</sub>-Bentheimer sandstone-water systems was investigated by means of visual contact angle measurements at 45°C and pressures between 0.1-14 MPa in a modified pendant drop cell (PDC) that allows captive-bubble contact-angle measurements at elevated temperatures and pressures [50]. Contact angle measurements were performed with water that was fully pre-saturated with CO<sub>2</sub>. It showed that the contact angle and the size of the bubble converge to equilibrium in time. During this convergence period, the contact angle and the bubble size generally show a slight change as function of time. The experimental data shows a larger dependency of the contact angle on bubble size than on pressure. However, for bubbles with similar size, contact angle shows a slight increase as function of pressure. All data shows that Bentheimer-water- CO<sub>2</sub> systems remain water-wet even at high pressure.

Martavaltzi et al. (2012) studied the effect of non-ionic surfactants on contact angle with limestone outcrop core samples [51]. Indiana Limestone core samples with gas permeability ranging from 2 to 4 md were used for contact angle measurement after equilibration with different brine solutions. A 1.5 wt% naphthenic acid in decane, deionized water (pH=7.15, resistivity 305 ohm) was used for preparation of all the brines. Formation Brine is a mixture of 2.577M NaCl, 0.476M CaCl<sub>2</sub>, 0.101M MgCl<sub>2</sub> and 0.003M Na<sub>2</sub>SO<sub>4</sub>. An inverted needle was used for sessile drop measurement to create a drop on model oil. Results show that higher salinity tended to increase the contact angle for most of the ions studied. Sulfate ions alone do not reduce the contact angle. Addition of non-ionic surfactant in 0.01M CaCl<sub>2</sub> did not induce significant improvement on the wettability of the calcite samples. The presence of the 2 first members of the 15S analogous series (secondary alcohol ethoxylates are termed 15-S in this work) led to only marginal decrease of the contact angle. Contact angle measurements on porous samples from outcrop were close to those on calcite crystals and exhibited similar trends with ionic compositions. This suggests that valid contact measurements may be made on thin end- pieces of reservoir core samples

Mirchi et al. (2014) studied the behavior of several anionic surfactants in the presence of crude oil 80°C [52]. The results of these tests were used to find the best surfactants. Then dynamic interfacial tensions and contact angles of selected surfactant-in-brine/oil/shale system was measured by the rising/captive bubble technique (axisymmetric drop shape analysis). Using the same methodology, the effects of surfactant concentration (0.01 to 0.1 wt. %) and brine salinity (0.1 to 5 M NaCl) on IFT and CA at ambient and reservoir conditions (i.e. 80 °C and 3000 psig) were studied. Surfactant adsorption on shale

samples was also measured in brines at ambient conditions. It was revealed that the anionic surfactant reduced the interfacial tension of oil and brine from 23 to 0.3 mN/m at 5 M salinity. Adding surfactant into the brine increased the dynamic contact angle on the shale samples. The maximum contact angle values observed in this study were generated with surfactant concentrations close to CMC (critical micelle concentration). The anionic surfactant was more effective in increasing the contact angle and reducing the IFT at reservoir conditions than ambient conditions. Introduction of surfactant into the fluid system resulted in a significant reduction in contact angle hysteresis.

Alshaikh and Mahadevan (2014) performed sensitivity analysis of ion composition on wettability of carbonate rock samples [53]. They tried to identify the impact of six salts and three interactions. They concluded that the chlorides have the maximum impact on the contact angle change to water-wetness (22% and 31 % respectively for sodium and calcium salts). Reduction in chlorides has the obvious benefit of changing the contact angle to more water-wet. Sodium chloride and calcium chloride are the major salts that alter the calcite wettability. The percentage contributions were 22% and 31% for sodium chloride and calcium chloride, respectively. Some salts are affected due to the interactions with other salts. In this study and design of experiments these interactions were examined: the interaction between sodium chloride and sodium sulfate, the interaction between sodium chloride and magnesium chloride, and the interaction between sodium chloride and calcium chloride. The optimum brine salinity was determined after conducting 27 contact angle experiments. The optimum brine salinity consists of different salt combinations and different salt concentrations. The optimum brine was prepared by mixing 80 gm of NaCl, 0.21 gm of Na<sub>2</sub>SO<sub>4</sub>, 63 gm CaCl<sub>2</sub>, 13.8 gm

of MgCl<sub>2</sub>, 0.1 gm of MgSO<sub>4</sub> and 0.1 gm of CaSO<sub>4</sub> in one liter of DI water. A confirmation experiment using the optimum brine was performed at the reservoir pressure and temperature. The measured contact angle was 28.9° with brine salinity of 157,207 ppm.

Jaeger et al. (2010) conducted study for a thorough experimental description of a gas-crude oil-reservoir water system and its behavior under CO<sub>2</sub> pressure including oil density and interfacial properties [54]. They generated a drop of oil in a mixture of CO<sub>2</sub> and Oil. The density of CO<sub>2</sub> and oil mixture was measured using a gravimetric method by exposing the oil to carbon dioxide at different pressures. It was concluded that because of its strong ability to dissolve in hydrocarbon fluids, carbon dioxide has a considerable effect on phase behavior and IFT in oil and gas reservoirs. In the presence of light hydrocarbons, complete miscibility is achieved at moderate pressures. As a consequence, the IFT decreases rapidly by increasing the pressure and ultimately vanishing at the point of complete miscibility. IFT of crude oil in a CO<sub>2</sub> atmosphere significantly decreases but reveals the difference in miscibility at 40 and 80°C by exhibiting higher IFT at higher temperatures. Further, carbon dioxide has a significant effect on the IFT in a crude oil-aqueous solution system, which influences the wetting via the Young's relationship. Dynamic studies reveal that the wetting liquid penetrates into porous rock structures, whereas drops of the non-wetting liquid maintain their shape after the adjacent liquid phases are saturated with carbon dioxide and an equilibrium CA is established.

Alidad (2001) in his PhD thesis has provided the dependence of contact angles and line tension on drop size by providing data of 27 solid-liquid-vapor systems [16]. He provided

that line tension ranges from  $10^{-7}$  J/m for systems with low contact angles to  $10^{-4}$  J/m for high energy system studied.

Kwok and Neumann (1999) discusses a review and comparison of different contact angles measured and their limitations and also generated contact angle data by using a goniometer and also by ADSA method and then used different approaches such as the three surface tension interpretation approaches (Fowkes approach, Owens-Wendt-Kaelble approach, and Lifshitz-van der Waals approach) and Equation of state approaches (Antonow's rule, Berthelot's geometric mean combining rule, modified Berthelot's rule) and then compared the results to provide positivity and limitation of each method [55].

Yuan and Lee (2013) highlighted the comparison of telescope-goniometer method, the Willhelmy balance method and DSA method [56]. Telescope-goniometer has the advantage of simplicity and that only small amounts of liquids and small surface substrates are required. However there are high risk of impurities. Captive bubble method provides better results as compared to sessile drop but it requires far more liquid which can be problematic when the solid swells after immersion into liquid or when a film on the solid is dissolved by the liquid. Willhellmy method is also a more accurate method for contact angle measurement as it measures the weight and length of the solid samble which can be measured with high accuract and also the measured force is an averaged value. But it has drawbacks that the solid sample must have uniform cross-section in the submersion direction. Sample must have same composition and topography at all sides which might be difficult to meet. Also a sufficient quantity of luquid must be used, which might cause the solid sample to swell and/or absorb vapor unintentionally. The ADSA technique is believed to be one of the most accurate techniques for high precision contact

angle measurement. With a reproducibility of  $\pm 0.2^\circ$ , the ADSA method has been shown to improve the accuracy of contact angle measurement by essentially an order of magnitude, compared to the reproducibility of  $\pm 2^\circ$  by direct tangent measurements.

# **CHAPTER 3**

## **RESEARCH METHODOLOGY**

For our research, IFT700 apparatus was used to study the change in interfacial tension at different temperatures, pressures, brine salinities, oil types and surfactant types. The apparatus consists of two manual pumps equipped with the pressure gauge, a viewing chamber (VC): whose temperature is controlled by PT100 (temperature controller) and also equipped with piezoelectric pressure transducer, Video system: 1 CCD color camera 1.4 Mega pixel, 1 macro zoom lens, 1 LED for lighting. The data acquisition is done from a DELL PC attached to the equipment with IFT software installed. In order to maintain high pressure, a pump has been used. This same equipment was used for contact angle measurements. A brief description of all the methods used in this work, the materials and the equipment as well as the detailed procedure followed in the experiments is described below.

### **3.1 Analysis of Interfacial measurements**

#### **3.1.1 Drop Shape Analysis:**

Drop shape analysis consists of different procedures to analyze the shape of a fluid drop in order to extract its properties. The principal assumptions are

- The drop is symmetric about a central vertical axis: this means it is irrelevant from which direction the drop is viewed.

- The drop is not in motion in the sense that viscosity or inertia are playing a role in determining its shape: this means that surface (or interfacial) tension and gravity are the only forces shaping the drop.

The two principal practical advantages of the technique are

- Calibration is straightforward in that only optical magnification is needed. This can be measured with high accuracy and is easy to trace to national standards. (Density must be known by this and all methods.)
- Solid surfaces of the apparatus involved need not have any special cleanliness because their wettability, per se, does not affect the result. This is a significant advantage over such techniques as the Wilhelmy plate where cleanliness is required [57].

### **3.1.1.1 Drop Shape Analysis (DSA) Methods:**

Drop Shape Analysis is the analysis of a drop generated inside a fluid for interfacial tension or contact angle measurement with a solid surface. In historical goniometer, the drop shape analysis was done by aligning a tangent to the drop by hand on scaled rotating disk. Today the optical evaluation is a modern technique which is carried out by camera and software which provides better accuracy with high-resolution reproducibility that helps to consider maximum points on the drops. This modern method on one hand is a good step however on the other hand it required more know-how and training of the user for the equipment.

Bulk Fluid is the fluid where the drop is released. For example, a drop of oil inside water; the bulk fluid is the water. Or a drop of water inside air; the bulk fluid is air. And the

fluid of the drop is called Drop Fluid. Before carrying out the drop shape analysis, the drop configuration must be selected in the software along with the calibration of the cell. The drop configuration describes the arrangement of drop fluid in the image. There can be the following configurations:

**Sessile Down:**

It is an experiment to measure contact angle, where the drop fluid density is higher than the bulk fluid density. It means the needle is on the top of cell. For example: a drop of oil inside gas released on a rock plate.

**Sessile up:**

It is an experiment to measure contact angle, where the drop fluid density is smaller than the bulk fluid density. It means the needle is on the top of cell. For example: a drop of oil ( $>10^\circ$  API) in water released on a rock plate.

**Pendant Drop:**

It is an experiment to measure IFT, where the drop fluid density is higher than the bulk fluid density. It means the needle is on the top of cell. For example: a drop of water in air.

**Rising Drop:**

It is an experiment to measure IFT, where the drop fluid density is smaller than the bulk fluid density. It means the needle is on the bottom of cell. For example: a bubble of air inside water.

### **3.1.2 Models for Analysis**

#### **Circle Method**

Circle method is also called height-width method. In this method the height and width of the rectangle enclosing an arc (arc is assumed to be the drop of fluid on a solid surface as a part of complete circle) are determined. This method has a disadvantage that it uses only a few pixels at the point of inflection and at both sides instead of the whole contour. The measurement is therefore suspected to be affected by interference in this area.

#### **Polynomial Method/Tangent Method 1**

Polynomial method evaluates only the region where the phases come into contact. Therefore a drop of any geometrical shape can be measured and the polynomial adapts itself to any curve that can be thought of at the contact point of the three phases. This method can be used for inclined or very asymmetrical drops.

#### **Conic Section Method/Tangent Method 2**

Conic section method assumes an elliptical drop shape and the contact angle is determined as the angle between the baseline and the tangent at the conic section curve at the contact point of three phases.

#### **Young-Laplace method**

This method is suitable for symmetrical drop shapes that are unaffected by interferences such as sample tilting or contact with the capillary needle. It can be used to measure angles above 10°. Also it cannot measure dynamic contact angles because this method is

sensitive to the contact between the drop and the needle. This method analyzes the drop shape as an effect influenced by the gravity.

### Choice for Method in this work

Circle method provides good results for contact angles very low up to 20°, conic section method can provide up to 100° and polynomial and Young-Laplace provides throughout the whole measuring range above 10°. Also for higher drop sizes, polynomial or Young-Laplace can be used. For asymmetrical drops, only the two tangent methods can be used however circle and Young-Laplace methods give good results for symmetrical (no-inclination) drops because they produce a single contact angle. Table 1 by Kruss [58] has provided the summary of all DSA methods

Table 1: DSA methods

	Circle	Conic section	Polynomial	Young-Laplace
<b>Measuring range</b>				
0-20°	✓			
10-100°		✓	✓	✓
100-180°			✓	✓
<b>Drop weight (volume*density)</b>

Static (contour without needle)	✓	✓	✓	✓
Dynamic (contour with needle)		✓	✓	
<b>Contour shape</b>				
Symmetrical	✓	✓	✓	✓
Slightly asymmetrical		✓	✓	
Very asymmetrical			✓	

### **3.1.3 Static or Dynamic Measurements:**

#### **3.1.3.1 Contact Angle:**

When the three-phase-line of contact angle is in actual motion, the contact angle produced is called a dynamic contact angle. In actual the solid drop moves in order to wet the fresh surface with time. In order to measure this kind of dynamic contact angle, the liquid drop is expanded and contracted with time on the surface of the solid. They are called advancing or receding contact angles respectively. These angles fall within a range, with the advancing angles approaching a maximum value, and the receding angles approaching a minimum value. Dynamic contact angles can be measured at various rates of speed. At a low speed, it should be close or equal to a properly measured static contact angle. The difference between the advancing angle and the receding angle is called the hysteresis.

However, on ideal solid surfaces, there is no contact angle hysteresis. On smooth but chemically heterogeneous solid surfaces, the experimentally observed contact angle may vary in each experiment and cannot be generalized. It is recommended to have a solid surface as smooth as possible but however there are no general guidelines regarding for surface roughness so as not to affect the contact angle.

In our work, both static and dynamic contact angles have been recorded however there is no induced change in volume of the drop. The change is caused either by solubility of bulk and drop fluids, or adsorption effect onto rock disk.

### **3.1.1.1 Interfacial Tension:**

Interfacial tension measurement is influenced by the time of contact between two fluids in order to allow the diffusion of both fluids and come to equilibrium. This diffusion measured with time provides the dynamic interfacial tension of the drop fluid with bulk fluid. Static interfacial tension is the one at which there is no change in interfacial tension with time.

In this work, both dynamic and static interfacial tensions have been recorded and provided.

## **3.2 Pendant Drop IFT Technique**

Pendant drop technique is a static method based on the droplet shape when the drop is at mechanical equilibrium. This technique is the most adaptable method for wide range of temperatures and at high pressures [59]–[61]. Unlike other empirically derived techniques, pendant drop method uses a force balance between buoyancy and gravitational forces. This force balance defines the shape of the drop-fluid hanging out of a capillary tube (needle) immersed in the bulk fluid. Shape of the drop is analyzed at mechanical equilibrium conditions. If the two fluids are immiscible, an interface will develop between the two fluids and the curvature of this interface depends on the pressure-differential between the two fluids. A form of Laplace-Young equation describes the condition of mechanical equilibrium that governs the pendant drop.

A droplet shape is assumed spherical therefore  $P_{int}$  is the pressure inside the droplet and  $P_{ext}$  is the pressure outside. If equilibrium state is reached, the energy required to increase or decrease the droplet volume is positive. In other words, this state matches to the minimum energy level. The energy to increase the droplet volume is ( $-P.dV$ ):

$$\delta W_{volume} = -(P_{int} - P_{ext})\delta V$$

Hence increasing the energy of surface area, it induces:

$$\delta W_{area} = \gamma \delta A$$

Where  $\gamma$  is the interfacial tension; which means that the infinitesimal energy variation to modify the radius of a spherical droplet is

$$\delta W = -(P_{int} - P_{ext})\delta \left(\frac{4\pi R^3}{3}\right) + \gamma \delta(4\pi R^2)$$

$$\frac{\delta W}{\delta R} = 0 = -(P_{int} - P_{ext}) \times 4\pi R^2 + \gamma \cdot 8\pi R$$

Or,

$$(P_{int} - P_{ext}) = \frac{2\gamma}{R}$$

Internal pressure is higher than external pressure, more exactly; the pressure of convex side is bigger than the concave one. Therefore, the argument does not depend of the phase nature of the droplet (liquid droplet inside a gas or gas droplet inside a liquid). This relation can be extended to the shape of a real droplet. At each point of the surface area of the droplet, curve radius  $i R_i$  can be defined. Let  $S$  be a surface (separation fluid A/fluid B) as in Figure 1 defined by the curves  $dl_1$  and  $dl_2$ , centered in  $O_1$  and  $O_2$ , with radius  $R_1$  and  $R_2$ . In  $O$ , at equilibrium, a force  $f$  counterbalances the vertical resultant force from interfacial tension:

$$\Delta P \cdot S = \Delta P \cdot dl_1 \cdot dl_2$$

$$f_i = \sigma \cdot dl_i$$

$$\Delta P = 2\sigma \left( \frac{\cos \alpha_1}{dl_1} + \frac{\cos \alpha_2}{dl_2} \right)$$

$$(P_{int} - P_{ext}) = \gamma \left( \frac{1}{R_1} + \frac{1}{R_2} \right)$$

Moreover, taking into account the fundamental equation of the equilibrium of the forces at a point of the drop, ( $\Delta P \cdot S = m\vec{g}$ ). Taking into account, any kind of drop, the Laplace equation is:

$$\frac{dx}{ds} = \cos\theta, \quad \frac{dz}{ds} = \sin\theta,$$

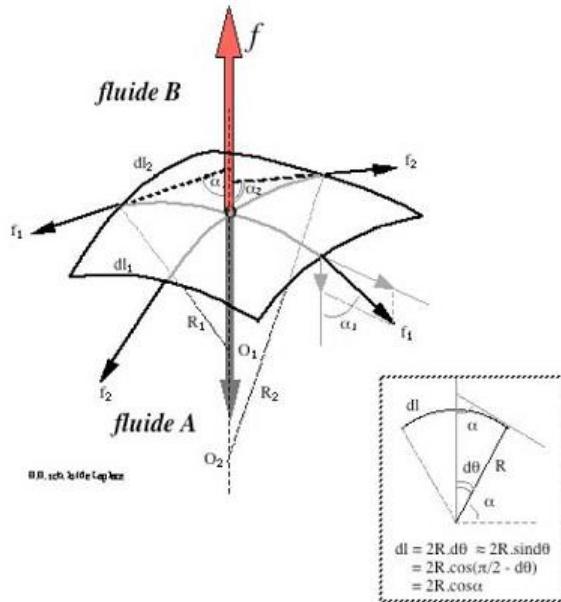

Figure 1: Force Balance of Interfacial Tension

This equation (1) does not have analytical solution and a numerical solution is required. Vinci Technologies has developed house software dedicated for oil & gas laboratory to provide accurate and fast results. An old generation of IFT softwares used only two or three main parameters (Equatorial diameter, Apex diameter, refer to Adamson table) to compute the IFT. Subsequently the accuracy of the results was based on only few parameters. To enable maximum accuracy, all the points from shape of the drop are taken

into account to solve the Laplace equation. Fast computation is performed thanks to an advanced numerical scheme of resolution. To sum up, the IFT700 enables to determine the interfacial tension from the Laplace-Young equation based on the complete shape of the droplet [62].

### **3.3 Sessile Drop and Contact Angle (Young's Angle)**

A way to study liquid-solid interaction resides in leaving a fluid-droplet on a cleaned and polished area of a solid. It is called sessile droplet (in opposition with pendant/rising droplet). The droplet would spread over the face even more solid-liquid interactions are more “attractive” than the liquid-liquid ones. Making sure that equilibrium state is reached (many minutes can be required); contact angle (also called Young’s angle) can be measured.

For tension between liquid and gas, tension between solid and gas and tension between liquid and solid. At each interface, tension is not equivalent, and equilibrium state means:

$$\gamma_{liq-gas} \cdot \cos\theta + \gamma_{liq-solid} = \gamma_{solid-gas}$$

$$\gamma_{liq-gas} \leftrightarrow \sigma_l \text{ and } \gamma_{solid-gas} \leftrightarrow \sigma_s$$

As the measurement of interfacial tension, the IFT700 enables to determine the contact angle thanks to computer processing of video frames. Liquid can be classified according to this angle. For “wetting liquid”, the contact angle reaches very low values.

## 3.4 Materials

### 3.4.1 Core Sample

Guelph Dolomite core of 12" length and 1.5" diameter were used in the experiments. The core samples were procured from Kocurek Industries (USA). The porosity of the cores lies in the range of 10% – 19%. The supplier specified brine permeability was in the range of 45-100 md and gas permeability was in the range of 100-170 md. In addition, the core samples contain 98% dolomite with minute traces of silica.

### 3.4.2 Brine

Brine was prepared as synthetic sea water by using the salts mentioned in Table 2:

Table 2: Components of Brine 1

Salt Name	Mg/L (ppm)
NaHCO <sub>3</sub>	165.246
Na <sub>2</sub> SO <sub>4</sub>	6339.02
NaCl	41172.4
CaCl <sub>2</sub> .2H <sub>2</sub> O	2387.13
MgCl <sub>2</sub> .6H <sub>2</sub> O	17644.1
<b>Total</b>	<b>67707.9</b>

Other three brines were prepared by diluting this brine by 50%, 25% and 12.5% with deionized water.

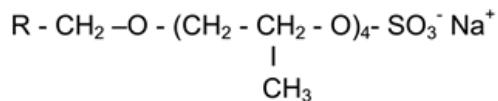

### **3.4.3 Surfactants**

Surfactants used in this work are :

- 1- Alfoterra L167-4S 90
- 2- Armovis EHS
- 3- FS-50

#### **3.4.3.1 Alfoterra**

Anionic surfactants are surface-active agents having a net negative charge. Alfoterra L167-4S 90 (a branched alkyl alcohol propoxy sulfate) is an anionic surfactant containing 4 moles of Propylene oxide (PO) distributed by “Sasol North America Corporation”. It has the following chemical structure:

$\text{R} = \text{C}_{15}\text{H}_{31}$  or  $\text{C}_{16}\text{H}_{33}$  (linear & mono-branched carbon chain)

These anionic surfactants are good candidates for EOR because they create very low IFT at very low concentrations and without any co-surfactant or alkaline agent [63]. Alfoterra L167-4S 90 is best suited for use at low temperature (less than 60°C) and salinities below 40,000 ppm.

It exhibits unique extended surfactant structures allowing improved solubilization of oily materials in an aqueous medium by extending the interface. The monobranched alkyl hydrophobe allows for greater interaction with the oil phase while maintaining good solubility.

#### **3.4.3.2 Armovis EHS**

“Armovis ® EHS” by “AkzoNobel” is a patented viscoelastic surfactant (VES) that offers a range of unique benefits when used in acidizing of hydrocarbon-bearing

carbonate reservoirs. It is zwitterionic and contains 50% total solids with 1 specific gravity and PH of 8.

In case of VES surfactants when certain salts are present in the aqueous fluid within a particular concentration range, the micelles assume a rod-like structure similar to polymer strands. These spherical (rod-like) micelles becomes entangled, viscoelastic behavior develops, and fluid movement is hindered. However this packing is affected by conditions such as temperature and surfactant concentration. Also it may be influenced by changes in micelle chain length and dissymmetry that cause an increase in surfactant's spontaneous curvature, ultimately determining whether surfactant's molecules will form spherical or cylindrical micelles [64].

Viscoelastic surfactants have been for mobility control and lowering the IFT [65]. They are found to form foam with CO<sub>2</sub> and have been used in some studies as a fracturing fluid where VES fluids were found to be compatible with CO<sub>2</sub> [66], [67].

### **3.4.3.3 FS-50**

FS-50 is an amphoteric fluorosurfactant that significantly reduces the surface tension of aqueous solutions and is also useful in providing sustained foam. Fluorosurfactants are synthetic organofluorine chemical compounds made up of multiple fluorine atoms. As surfactants, they are more effective at lowering the surface tension of water than comparable hydrocarbon surfactants. They have a hydrophilic head and a fluorinated tail. Some fluorosurfactants, such as PFOS, are detected in humans and wildlife. It is based on six flourinated carbon molecules that cannot break down to PFOA in the environment.

The electronegativity of fluorine reduces the polarizability of the fluorinated molecular surface due to which they are not susceptible to London dispersion force due to which they are lipophobic. The carbon-fluorine bond is quite strong which makes it suitable for the fluorosurfactants to be used in harsh conditions.

#### **3.4.4 Deionized Water**

First grade deionized water was used for preparation of Brines and surfactant solutions. In addition, it was also used to clean the entire IFT Equipment before and after each experiment in order to avoid presence of any impurity inside the cell.

#### **3.4.5 Oil**

Following Oils were used in this experiment:

- 1- Crude oil 1: Arabian Oil of API 30°
- 2- Crude Oil 2: Arabian Oil of API 40°
- 3- Model Oil 1: 98% Squalane ( $C_{30}H_{62}$ ) a colorless odorless hydrocarbon with API 43°
- 4- Model Oil 2: 99% Pure Toluene
- 5- Model Oil 3: 99% Pure Penta-decane ( $C_{15}H_{32}$ )

Properties of Crude Oil 1:

<b>Percentage of Aromatics</b>	<b>Percentage of Saturates</b>	<b>Percentage of resins</b>	<b>Percentage of Asphaltenes</b>
49.51	35.36	11.64	3.49

Properties of crude oil 2:

Percentage of Aromatics	Percentage of Saturates	Percentage of resins	Percentage of Asphaltenes
57.90	32.84	8.66	0.63

### 3.4.6 Gas

The following two gases were used in the experiments:

- 1- Industrial grade N<sub>2</sub> gas was obtained in sufficient quantity in the form of gas cylinders. Nitrogen gas was used to provide pneumatic control to the ISCO pump for pressurizing the CO<sub>2</sub> accumulator.
- 2- 99% pure CO<sub>2</sub> in the form of gas cylinders was obtained.

### 3.4.7 Toluene

Pure Toluene was used during this experiment as a solvent for cleaning the IFT equipment, accumulator and densitometer.

## 3.5 Equipment

### 3.5.1 HPHT IFT Equipment

Vinci Technologies IFT700 (Figure 2) was used to measure interfacial tensions and contact angles. It consists of:

- Two manual pumps equipped with the pressure gauge, one is called drop pump and other is called bulk pump, both equipped with a temperature sensor and an electric heater. These pumps act as a storage for bulk and drop fluids and also contain valves that can be screwed to increase or decrease pressure. The drop fluid can be filled by an injector filled with fluid. However, in order to fill the

bulk pump, the fluid from the other injector has to pass through the cell in order to reach the bulk fluid. In the configuration used in this experiment, the injector of bulk pump has been replaced with the accumulator containing CO<sub>2</sub> and the bulk pump is not being used to pressurize the cell. The accumulator is being pressurized which causes an increase in pressure of the cell. The drop can only be generated when the pressure of drop pump is higher than bulk fluid

- A cell called viewing chamber in which the experiment takes place having the capacity of 20 cc fluid volume. It has maximum capacity of 10,000 psi with glass on both sides, one side allows the light source while the other side allows camera to capture the pictures.
- Capillary Needle which generates drop. This Needle is connected via a valve to drop pump. This equipment comes with different sized needles. Needle size depends on the viscosity of the fluid. Since no fluid of very high viscosity is to be used, therefore the smallest needle has been used.
- A control panel containing temperature regulator and pressure indicator. It does remain only on the time when equipment has to perform experiment. And it takes almost 5 to 6 hours for stabilization of a low temperature such as 30°C and take almost 1 hour for high temperatures such as 90°C. For 60°C it takes almost 1.5 to 2 hours.
- 1 CCD color camera 1.4 Mega Pixel and 1 LED light. The camera captures live video of the drop from which stills can be captured at particular moment. The

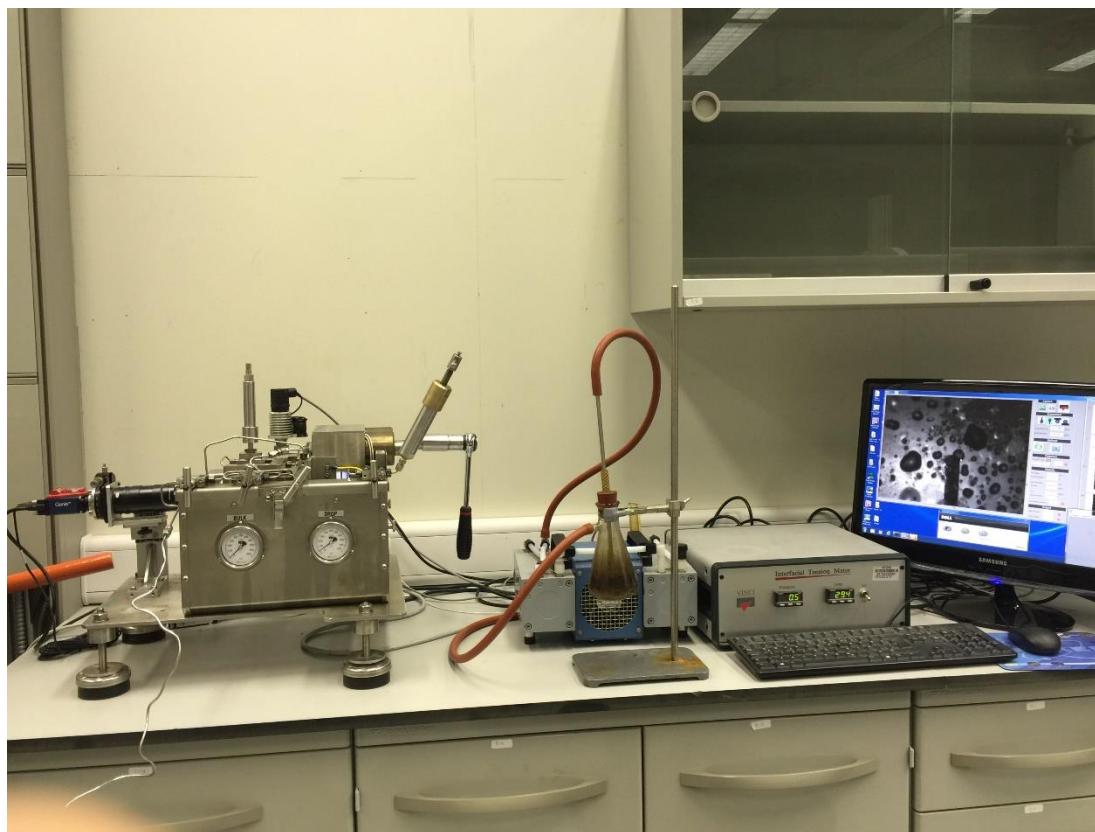

Figure 2: IFT Apparatus

Figure 3: DMA 4500 and DHA HP by Anton Paar

computer software can be set to take a picture after every 5 second in order to study the change in properties of the drop.

- Computer with IFT software installed. This software uses Drop shape Analysis technique and use Young-Laplace method. This software is calibrated for each experiment for being completely vertical and with stabilized pressure and clean glass and also proper focus.

Equipment Configurations:

1- For IFT:

- a. Pendant Drop: When Bulk Fluid is lighter than the Drop Fluid.
- b. Rising Drop: When Bulk Fluid is heavier than the Drop Fluid.

2- For Contact Angle:

- a. Sessile Down: When Bulk is lighter than drop fluid
- b. Sessile Up: When Bulk Fluid is heavier than drop fluid

### **3.5.2 ISCO Pump**

A pneumatic controlled ISCO syringe pump with automatic refilling capacity and two cylinders. Each cylinder had 265ml capacity, maximum 7500 psi pressure, and a flow rate of maximum 45ml/minute. This pump is connected to an accumulator of 5 litre capacity which contains high purity CO<sub>2</sub>. Figure 4

### **3.5.3 HPHT Densitometer**

Densitometer by Anton Par (DMA-4500) was used along with an HPHT accessory (DMA-HP) as shown in the Figure 3.

Figure 4: ISCO Pump with N<sub>2</sub> Cylinder for pneumatic control

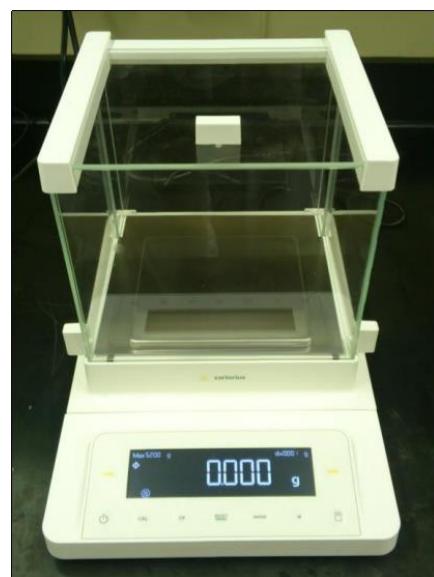

Figure 5: Analytical Weight Balance

Figure 6: Specially Fabricated Disk Holder for Grinding disks

### 3.5.4 Analytical Weight Balance

A high accuracy analytical weight balance (Sartorius Cubis® Precision Balance MSE5203S-000-DE) was used to measure the weight of the salts for brine preparation. The weight balance is shown in Figure 5.

### 3.5.5 Disc Holder

A grinder was used to make the dolomite disks smooth and horizontal. The disc was inserted in a fabricated holder (Figure 6) that could fit in the grinder.

## 3.6 Methodology

### 3.6.1 Experimental Plan

In order to study the IFT of various parameters on IFT and Contact Angle and to find a low IFT system, it was decided to conduct a number of experiments. The experimental layout was divided in four main parts:

- i. The first part deals measurement of IFT of CO<sub>2</sub> with four types of Brines with different salinities on 3 temperatures and 9 pressures each.
- ii. CO<sub>2</sub> with Brine-Surfactant Solutions containing three different types of surfactants on 3 temperatures and 9 pressures each.
- iii. CO<sub>2</sub> saturated with Brine-Surfactant Solutions inside the cell, with five different oils and that saturated CO<sub>2</sub> on 2 temperatures, and 9 pressures each.
- iv. The last part consists of making contact angle measurements in the last system that was selected for IFT, on a Guelph dolomite at one temperature and 9 pressures with different oils as drop fluids.

The parameters that were kept constant are:

- i. Surfactant Concentration:
  - For FS-50: 0.15%
  - Alfoterra 0.1%
  - Armovis: 0.1%
- ii. Brine-Surfactant concentration in Cell: 0.1 ml
- iii. Core: Guelph Dolomite
- iv. Brine for Brine-Surfactant Solutions: Brine 4

The parameters that were varied to study the IFT are mentioned below:

- i. Temperature
  - Experiments without Oil: 30, 60 and 90 C
  - Experiments with Oil: 30 and 60 C
- ii. Pressure: from 1500 to 5500 psi

- iii. Brine Salinities from: 67708 ppm to 8464 ppm
- iv. Oil types: Two crude oils and three model oils

An experimental layout for performing IFT has been given in Table 3:

Table 3 Experimental Layout for IFT Experiments

		Interfacial Tension (mN/m)			
Temperatures		30°C	60°C	90°C	Compositions
		Experiment Number			
<b>Pressures: 1500 to 5500psi each experiment number</b>	1	2	3		Brine1 with CO <sub>2</sub>
	4	5	6		Brine2 with CO <sub>2</sub>
	7	8	9		Brine3 With CO <sub>2</sub>
	10	11	12		Brine4 With CO <sub>2</sub>
	13	14	15		BSS1 with CO <sub>2</sub>
	16	17	18		BSS2 with CO <sub>2</sub>
	19	20	21		BSS3 with CO <sub>2</sub>
	22	23	24		CO <sub>2</sub> + BSS3 with Crude oil 1
	25	26	27		CO <sub>2</sub> + BSS3 with Crude oil 2
	28	29	30		CO <sub>2</sub> + BSS3 with Model oil 1
	31	32	33		CO <sub>2</sub> + BSS3 with Model oil 2
	34	35	36		CO <sub>2</sub> + BSS3 with Model oil 3

The parameters for Contact Angle Measurements are:

- i. Temperature: 60°C
- ii. Pressure: 1500 psi to 5500 psi
- iii. Rock Sample: Dolomite
- iv. Oil Types: Two crude oils and one model oil

An experimental layout for performing CA has been given in Table 4

Table 4: Experimental Layout for Wettability Experiments

### **3.6.2 Density Measurements**

The first step in conducting the IFT experiments was to determine the densities of the fluids. IFT software requires the densities of both the bulk fluid and the drop fluid. For bulk fluid, we use CO<sub>2</sub> in almost all of the experiments whose densities at required temperatures and pressures can be easily found in the literature. Therefore, only the densities of drop fluids were measured.

The densitometer was calibrated using N<sub>2</sub> and deionized water with known densities. Then values were recorded at desired pressure and temperature conditions and a formula (polynomial) was devised and added into the equipment software. Now the equipment became ready to measure densities of other fluids.

The 1<sup>st</sup> step consists of density measurements of 4 Brines, each at 30, 60 and 90°C and temperatures from 1500 psi to 5500 psi. An accumulator was filled with 35ml of Brine 1 and tightened closed. Then it was connected to the inlet of DMA HP. But the outlet was kept slightly open so as to allow the air in the pipelines to escape. Then the accumulator was pressurized to 100 psi. When the fluid filled DMA HP and started coming out of the outlet, the outlet was tightly closed and the apparatus was set to stabilize at a particular temperature, say, 30°C.

At that particular stabilized temperature and required pressure, say we started from 1500 psi, reading was taken. Then the pressure was increased to 2000 psi and temperature was again allowed to stabilize and then the reading was taken. This continued till 5500 psi.

Now to take readings at 60°C, the fluid inside the DMA HP was allowed to flow out and new fluid from the accumulator was allowed to displace it. Then similar procedure of

closing the outlet and temperature stabilization was carried out. Procedure was repeated for 90°C.

### 3.6.3 IFT Measurements

After measuring the densities of brines, the IFT experiment needs to be performed on each of the brine sample. Then the brine that shows lowest IFT will be selected for further experiments.

#### 3.6.3.1 Interfacial tension between CO<sub>2</sub> and Brines

The Table 5 shows labelling of brines for easy explanation. Brine 2, 3 and 4 are simple dilutions of Brine 1 as mentioned already. The experimental parameters for performing IFT measurements between Brine and CO<sub>2</sub> are shown in Table 6.

Table 5: Brine Labels

<b>Brines Labels</b>	<b>Salinity ppm</b>
Brine 1	67708
Brine 2	33854
Brine 3	16927
Brine 4	8463

Table 6 : Experimental Parameters for Brine- CO<sub>2</sub> IFT Experiments

<b>Experiment Parameters</b>	
<b>Drop Fluid</b>	Brine
<b>Bulk Fluid</b>	CO <sub>2</sub>
<b>Temperatures (°C)</b>	30,60,90
<b>Pressures (psi)</b>	1500 to 5500
<b>Brine Salinities (ppm)</b>	67708 to 8464
<b>Type of CO<sub>2</sub></b>	99% Pure

The view cell was thoroughly cleaned with toluene and deionized water and then dried with tissue and nitrogen was also circulated. The pipelines, valves, pressure gauges, bulk and drop pumps, injectors were also cleaned with toluene and deionized water and dried by vacuum pump to make sure no traces of water or impurity is left. Then the pipelines and cell was reconnected. Brine1 was injected through injector 1 keeping the valve for drop generation closed so that it may fill Drop pump 1. Then CO<sub>2</sub> was charged into the cell from the connected accumulator that was pressurized using an ISCO Syringe Pump. Then cell was then covered and the equipment was allowed to stabilize on 30°C. It takes almost 5 to 6 hours to stabilize on 30°C. After stabilization, the valve from the drop pump is slowly opened to allow the flow of fluid through the capillary needle. Due to this, the drop is formed at the tip of the needle by using a specially designed high pressure syringe delivery system. Some of the CO<sub>2</sub> enters the needle and pipelines therefore initially that CO<sub>2</sub> comes out of the needle followed by drop fluid. After the drop is formed in the CO<sub>2</sub>, its digital image is well focused and stored automatically in the computer memory. The IFT keeps decreasing with time till a point where it comes to an equilibrium with the bulk fluid. At this point the IFT is called “equilibrium IFT”. Both the IFTs changing with time and the ones when they came in equilibrium have been reported in this work. The output data of this DSA program also includes the radius of the curvature at the apex point, the volume and surface area of the brine drop. Each experiment gave readings at one temperature and nine pressures. After each experiment, the equipment was thoroughly cleaned with toluene and deionized water and then vacuum dried.

In order to take readings at 60°C the whole process from cleaning to drop generation and analysis was repeated. Similar case for readings at 90°C.

### **3.6.3.2 IFT measurements between Brine-Surfactant Solutions and CO<sub>2</sub>**

Brine 4 was selected from the experiments of the 1<sup>st</sup> step because it showed the lowest IFT. This Brine was then used to prepare three solutions for three different types of surfactants. Their name and composition has been mentioned in Table 7

Table 7: Brine-Surfactant Solution (BSS) Labels

<b>Brine-Surfactant Solution Labels</b>	<b>Composition</b>
BSS 1	Brine 4 containing 0.1 % Alfoterra
BSS 2	Brine 4 containing 0.1% Armovis
BSS 3	Brine 4 containing 0.15% FS-50

The experimental parameters for this Experiment have been given in the Table 8:

Table 8: Experimental Parameters for IFT measurement of BSS & CO<sub>2</sub>

<b>Experiment Parameters</b>	
<b>Drop Fluid</b>	Brine4 containing Surfactant
<b>Bulk Fluid</b>	CO <sub>2</sub>
<b>Temperatures (°C)</b>	30,60,90
<b>Pressures (psi)</b>	1500 to 5500
<b>Brine Salinity</b>	8464 ppm
<b>Surfactants</b>	FS-50, Alfotera, Armovis
<b>Type of CO<sub>2</sub></b>	99% Pure

The concentration of surfactants typically found in literature is 0.1% however, it was found that fluorosurfactants are effective till 0.15% and then a constant plateau is reached in terms of their ability to decrease IFT. Therefore, BSS3 contains 0.15% FS-50.

These brine-surfactant solutions were then used as drop fluids with CO<sub>2</sub>. The same procedure was repeated as in 1<sup>st</sup> step for both cleaning, filling and temperature stabilization. The readings in this case were also taken at 9 different pressures from 1500 to 5500 psi for each temperature 30°C, 60°C and 90°C.

IFTs were quite small and drops were unstable therefore the drops did not sustain for much longer time. However, their equilibrium IFT was recorded at a point where IFT stopped changing with time.

### **3.6.3.3 IFT Measurements between CO<sub>2</sub> (saturated with brine-surfactant solution) and Oils**

This part of experiment is different from the previous experiments because previous experiments were between two single phases. This one is between a two phase CO<sub>2</sub> i.e. CO<sub>2</sub> saturated with BSS 3. The reason for selecting BSS 3 is that it gave the lowest IFT as compared to the other two surfactants.

The experimental parameters of this experiment have been given in Table 9. Some drops of BSS3 were dropped inside the cell before closing it. Then the cell was filled with CO<sub>2</sub> and allowed to stabilize with temperature and come at equilibrium with BSS3. On the required temperature and pressures, reading were obtained one by one. Both Equilibrium and changing IFTs were recorded with time.

Although the CO<sub>2</sub> was saturated with BSS3, the density used for this experiment is the density of pure CO<sub>2</sub> since the two phases of Brine and CO<sub>2</sub> have very limited solubility, this difference in densities is expected to be close to the difference between pure brine and pure CO<sub>2</sub> at desired temperature and pressures. However, at low temperatures and high pressures, where change in density is small, errors in the phase densities can have large influence on the derived values of IFT. [31], According to Hebach et al. at pressures up to 30MPa and temperatures between 10°C and 50°C they found out that density of CO<sub>2</sub> rich phase did not differ from density of pure CO<sub>2</sub> within the experimental uncertainty of 0.15%.

Table 9: Experimental Parameters for IFT measurements of Oils & CO<sub>2</sub>-BSS3

Experiment Parameters	
<b>Drop Fluid</b>	Oil
<b>Bulk Fluid</b>	CO <sub>2</sub> and approx. 0.1ml BSS3
<b>Temperatures (°C)</b>	30,60
<b>Pressures (psi)</b>	1500 to 5500
<b>Brine Salinity</b>	8464 ppm
<b>Surfactant</b>	FS-50
<b>Type of CO<sub>2</sub></b>	CO <sub>2</sub> Saturated with Solution
<b>Oils</b>	Crude oil 1, 2, Model Oil 1,2,3

### 3.6.4 Contact Angle Experiments

After the completion of all IFT experiments, the next challenge was to perform contact angle experiments in the same manner and with the same components as used in the last IFT experiment i.e. all 4 fluids (CO<sub>2</sub>, Brine, Surfactant, and Oil) with dolomite rock.

### **3.6.4.1 Preparation of Dolomite Disks**

A core of Guelph Dolomite with properties mentioned in the previous chapter was cut into disks of 1 inch x 2.5 mm. Then these disks were polished by a grinding machine using a specially fabricated holder. These disks were then put in the respective oils for aging for 24hrs at 60°C because the experiments would be performed at 60°C. (Figure 7)

Figure 7: Dolomite disk aged in squalane, pasted on disk holder of the cell

Another method of polishing the disks by using silicon epoxy could also be used but it could alter the composition of the rock and also the contact angle. Three test experiments were performed with different disks to see what could be the effect of polishing method.

### **3.6.4.2 Procedure**

The disks after aging were pasted on the holder of the cell with a glue, making sure fingers don't touch the top side of the disc. Then the cell was closed after putting some drops of BSS3 inside the cell and allowed to stabilize at 60°C meanwhile CO<sub>2</sub> was also injected inside the cell. When the temperature stabilizes, the disc is analyzed for its surface. Sometimes a lot of foam accumulates on the surface of the rock. This foam would make it difficult for the camera to differentiate between foam and the oil drop. In

this case, leave the equipment for 6 hours for the foam to disappear. The foam is more when there is crude oil as compared to any single component model oil.

Since horizon of the disk is an important factor for solution of Young-Laplace equation on the drop, the disk is matched with a horizontal reference line to make sure it is horizontal.

At the desired pressure and temperature, a drop is generated from the capillary needle. Some CO<sub>2</sub> comes out of the needle followed by drop fluid. Since we have a disk below, therefore the valve is opened with much care so as not to allow more than one drop to come out of the needle and fall on the disk.

The size of the drop doesn't matter as long as the weight of the drop doesn't act. Therefore, the smallest needle was used for all experiments.

Then the drop was recorded and reading were taken for the whole time until the drop comes to an equilibrium with bulk fluid. For some cases such as Squalane at higher pressures the drop would disappear because it was partially miscible into CO<sub>2</sub>. Therefore, an equilibrium value was recorded because, although the squalane would be miscible the CO<sub>2</sub>, the drop would become smaller and smaller the contact angle remained constant even with the decrease of drop volume.

After taking the readings at a single temperature and pressure, it was desired to take readings at other pressure. However, the same place on the rock cannot be used because it has already wetted the specific surface of the rock. Therefore, there can be two ways, either to turn off the equipment, deplete the gas, clean the cell and the equipment, change the disk and perform the experiment on a new disk. Or any way one could change the

place of drop on the disk. The holder on the cell could be rotated which could change the place of the drop. Hence this second method was used for ease. After the reading was taken for one drop at one pressure, the disk was rotated a little bit to change the location, pressure was increased till the desired pressure and then a new drop was generated and made to fall on a new place on the disk. This however depends on the volume of drop generated on the rock surface. If the drop is of high volume and there is no space left on the rock surface to measure at next pressure, the experiment was to run all over again with a new rock sample at required pressure and temperature conditions.

At the all of the results from contact angle experiments and IFT experiments were compiled and conclusion was derived from the results. For some of the values of contact angle, the experiments were repeated to confirm the trend.

## **CHAPTER 4**

### **RESULTS AND DISCUSSION OF IFT EXPERIMENTS**

The main purpose of an EOR process is to reduce the oil saturation which therefore increases the oil recovery. An EOR process like Surfactant-Alternating-Gas is used when simple CO<sub>2</sub> or simple Water injection does not give significant results.

The interfacial tension between SAG fluids co-existing in the reservoir have been measured in this series of experiments whose experimental plan and procedure have been mentioned in the previous chapter. The results of each step are described in the sections below:

#### **4.1 Density Measurements:**

Densities of the following fluids which were needed for IFT experiments:

- 1- CO<sub>2</sub>
- 2- Brine 1
- 3- Brine 2
- 4- Brine 3
- 5- Brine 4
- 6- Brine4 containing 0.1% Alfoterra
- 7- Brine4 containing 0.1% Armovis
- 8- Brine4 containing 0.15% FS-50

9- Crude oil1

10- Squalane (Model oil 1)

11- Crude Oil2

12- Toluene (Model Oil 2)

13- Pentadecane C15 (Model Oil 3)

Density of Fluids increase slightly with pressure and decrease with temperature. Trends of different fluid densities have been below. Details of density values have been provided in Appendix A.

#### 4.1.1 Carbon Dioxide ( $\text{CO}_2$ )

Carbon dioxide follows the following phases at different temperature and pressure conditions.

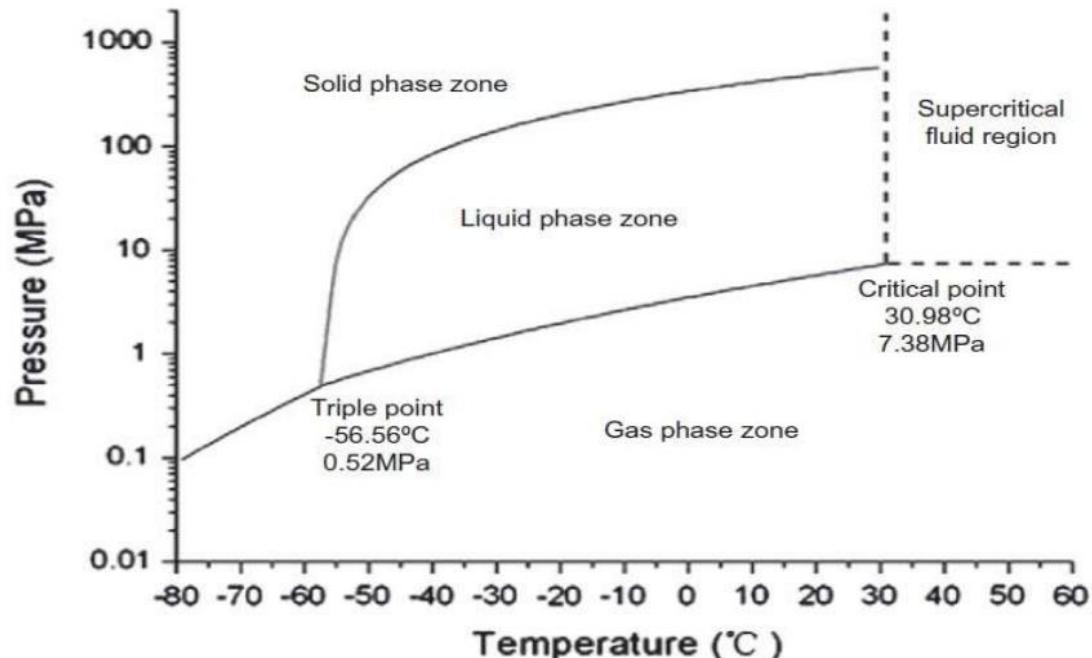

Figure 8: Phase Diagram of  $\text{CO}_2$  [36]

Density of CO<sub>2</sub> has been calculated by Ouyang (2011) correlation and given in Appendix A [68]. However the variation with pressure and temperature has been shown in Figure 9.

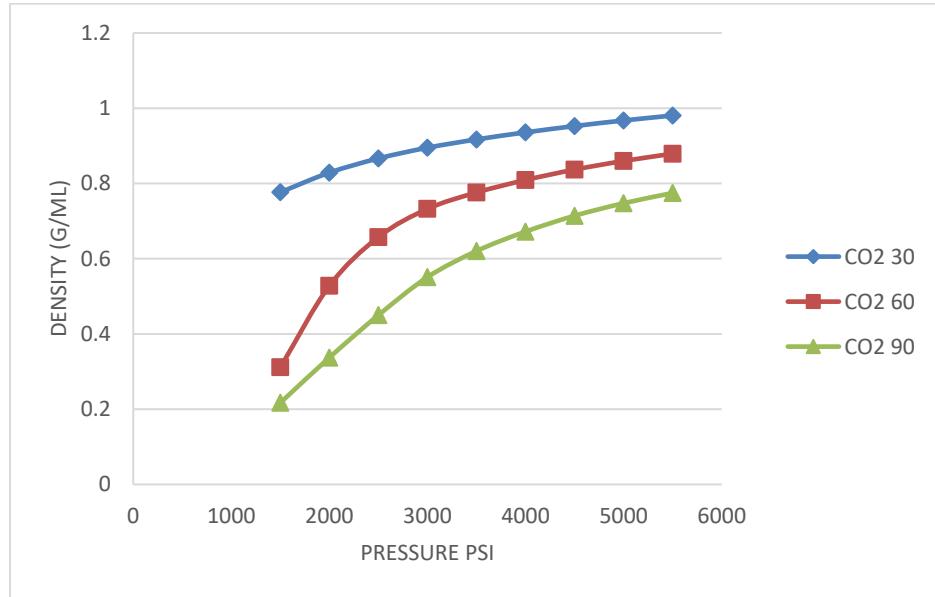

Figure 9: CO<sub>2</sub> Densities as a function of Pressure at Different Temperatures

#### 4.1.2 Densities of Brines:

The higher is the salinity, the denser is the brine as shown from the above figures. Also density increases with pressure and decrease with temperature.

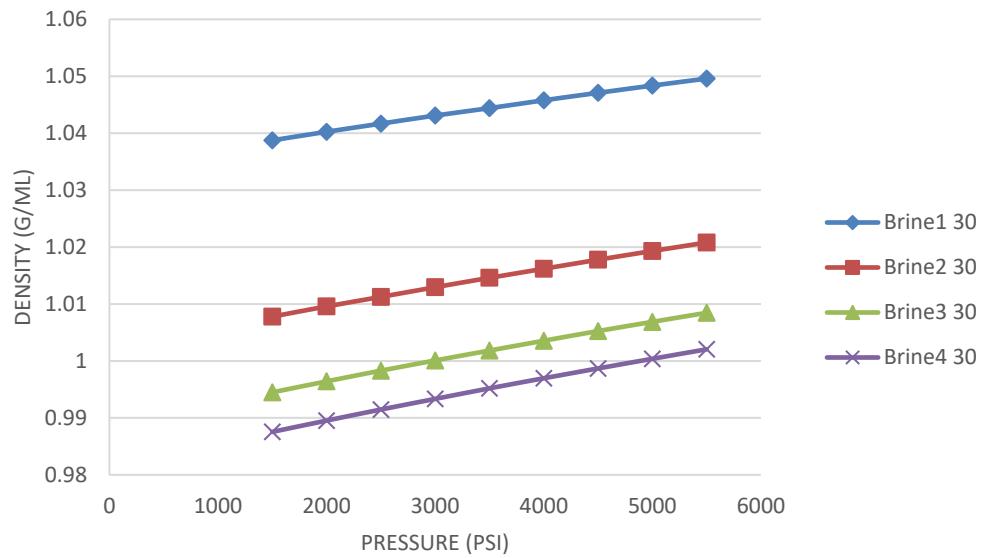

Figure 10: Densities of Brines at 30°C

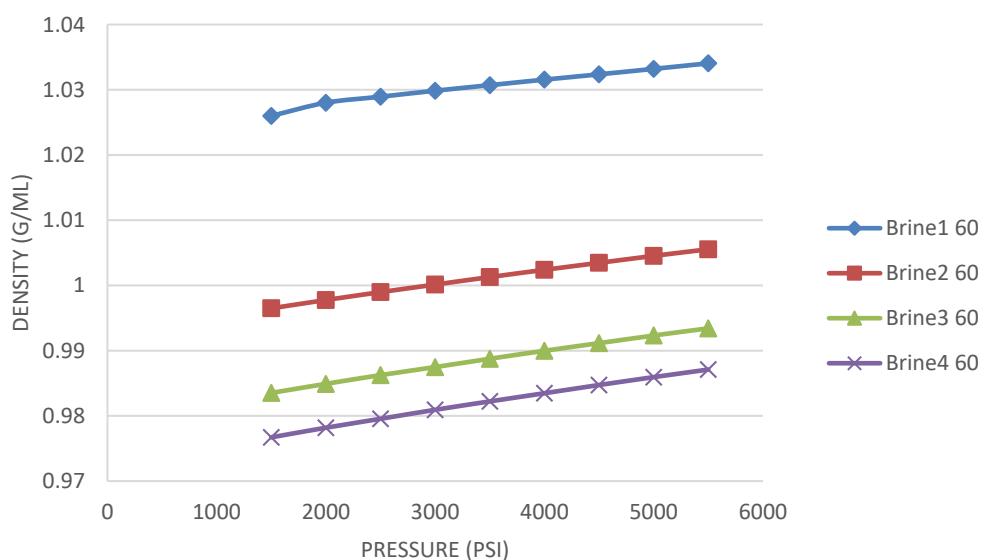

Figure 11: Densities of Brines at 60°C

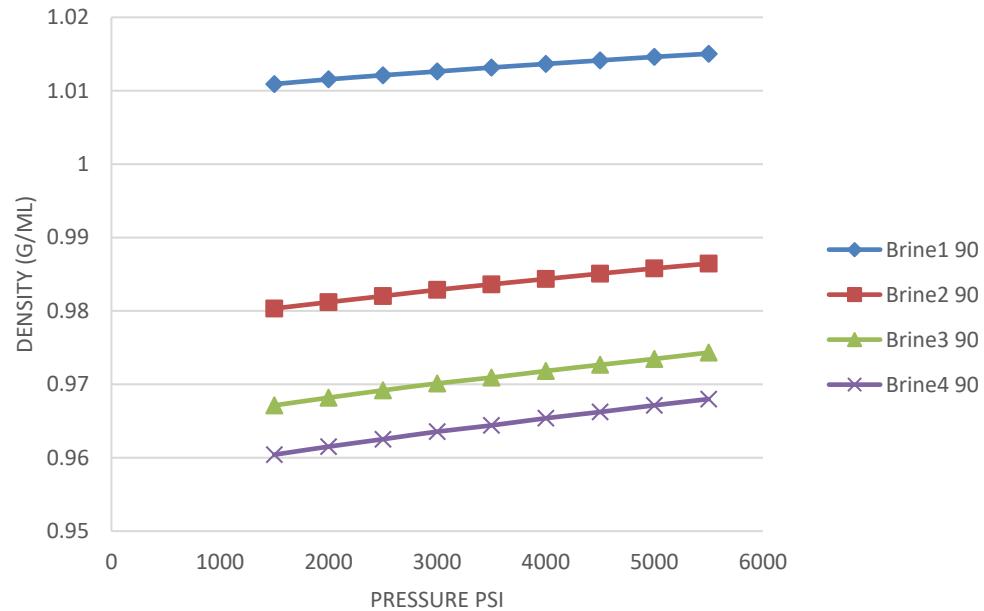

Figure 12: Densities of Brines at 90°C

#### 4.1.3 Density of BSS

In Figure 13 to Figure 15, for brine-surfactant solutions, density change is minute with pressure. The graphs have been drawn for small range to show the effect.

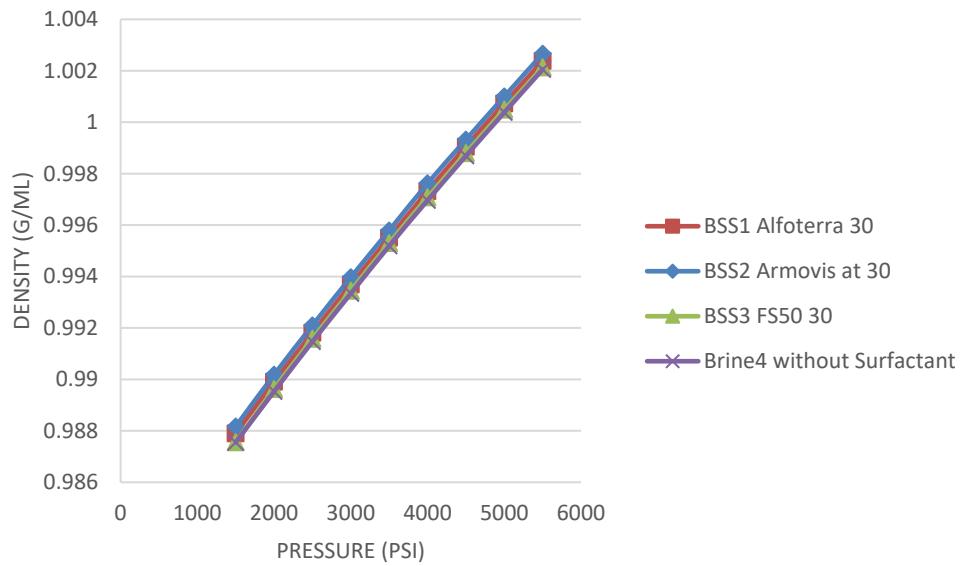

Figure 13: Densities of BSS at 30°C

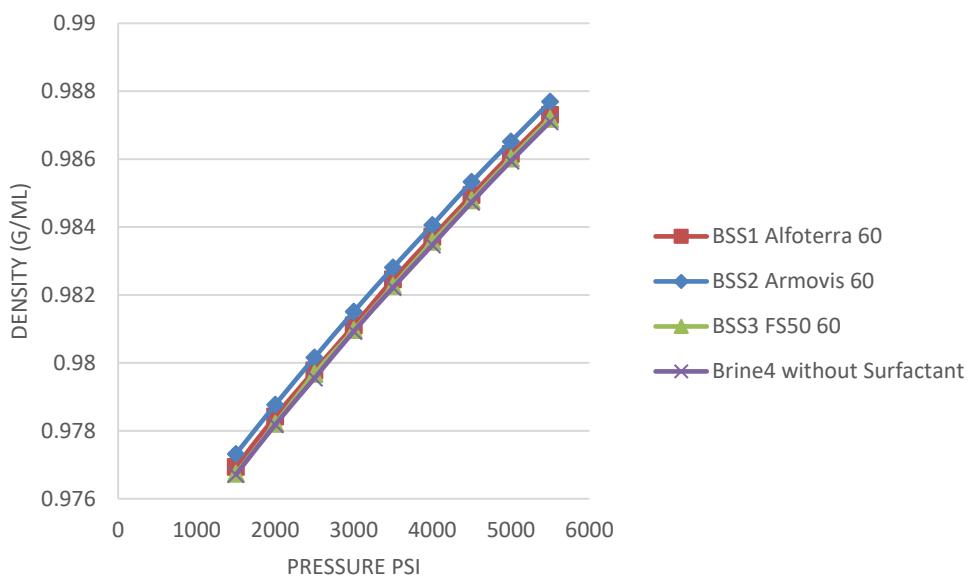

Figure 14: Densities of BSS at 60°C

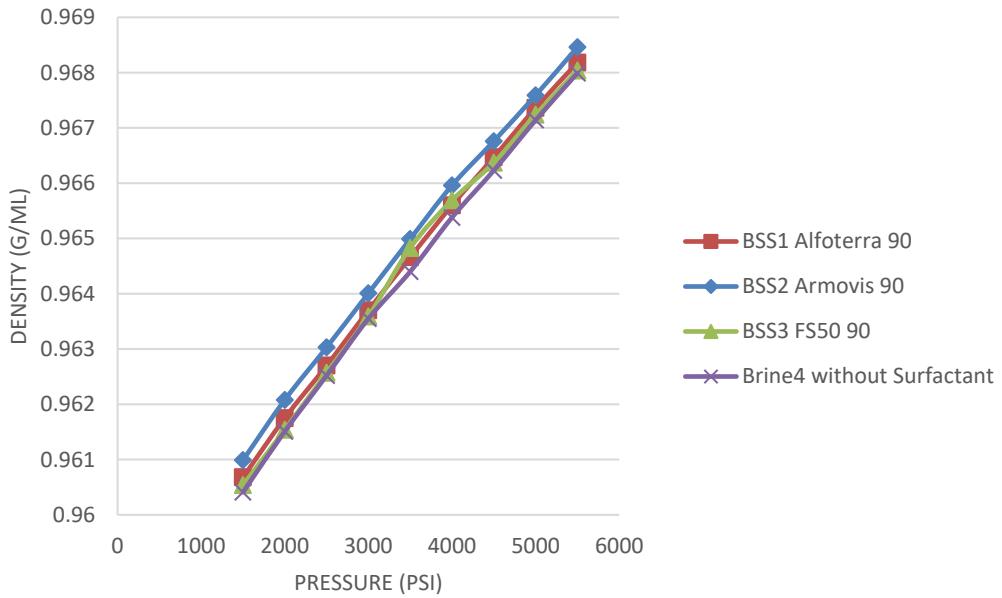

Figure 15: Densities of BSS at 90°C

#### 4.1.4 Density of Oils

Densities increase almost linearly with the increase in pressure and decrease in temperature. This trend is continuous for all fluids.

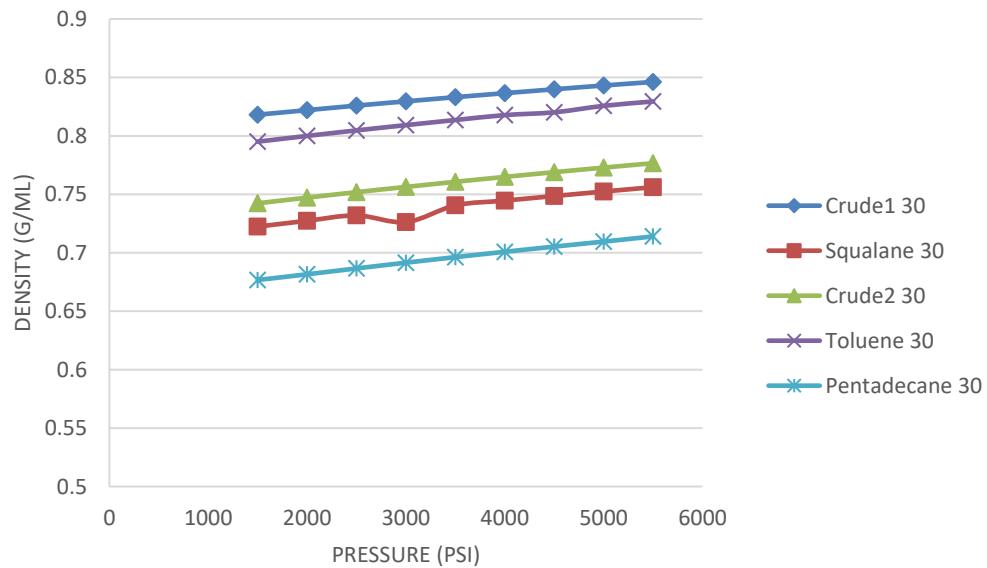

Figure 16: Densities of Oils at 30°C

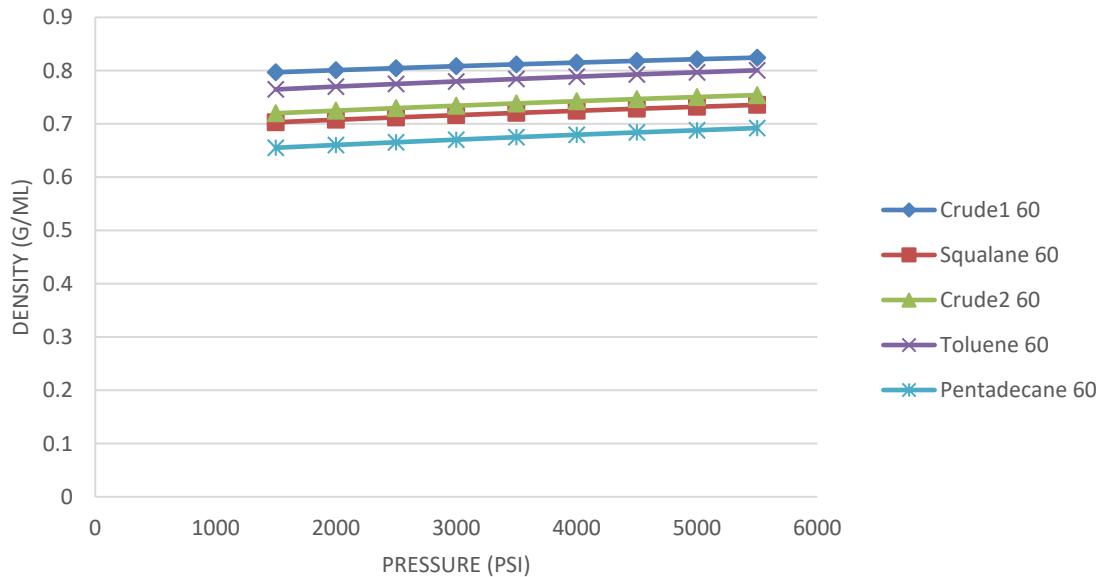

Figure 17: Densities of Oils at 60°C

## 4.2 IFT

According to the experimental plan mentioned in Table 3 interfacial tensions have been measured between the following fluids:

- 1- Brines as drop fluids and CO<sub>2</sub> as Bulk fluid
- 2- Brine-Surfactant Solutions as drop fluids and CO<sub>2</sub> as Bulk fluid
- 3- Oils as drop fluids with CO<sub>2</sub> as bulk fluid in the presence of brine-surfactant solution

### 4.2.1 Brines as drop fluids and CO<sub>2</sub> as Bulk Fluids:

#### 4.2.1.1 Effect of Temperatures and Pressures:

General trend found in literature is that higher is the temperature, higher is the IFT [18], [31]. However according to Chiquet et al. (2007) [69] IFT decreases with increase in temperature for water/CO<sub>2</sub> systems. According to Bikkina et al. (2011) [70] in the

supercritical region of CO<sub>2</sub>, the IFT with pure water is constant with both temperature and pressure. Yang et al. (2005) [38] found that IFT decreases with increase in pressure at 27°C but increase with increase in temperature, however they found that their brine was miscible at 58°C and 1100 psi since the interface disappeared.

In this work it was observed that brines with lesser salinity follow the trend observed by Li et al. (2012) that higher temperature causes increase in IFT and high pressure causes decrease in IFT [31]. For brine1, the brine with highest salinity, the IFT is independent of pressure and temperature matching with results by Li et al.

Initial decrease is high till 2000 psi at 30°C because at this point the system is in the supercritical phase at a point closer to gaseous phase (Figure 8). This rapid decline is due to solubility of CO<sub>2</sub> in brine according to Xing et al., (2013) [28].

At 60°C the IFT increases till 2500 psi. This behavior has been seen in the literature [70] but not highlighted and some authors have not measured values between these points. For Yang et al. (2005), at 58°C which is close to our temperature, the brine became miscible and no interface was formed [38]. Chun (1995) and Chalbaud et al. (2010) observed it at 71°C, Bikkina et al. (2011) at 40°C, Rocha et al. (1999) at 45°C, and Hebach et al. (2002) at 45°C, all in the same range of pressure that lie closer to points where CO<sub>2</sub> is behaving partly supercritical and partly gas [22], [39], [70]–[72]. Interestingly Hebach et al. (2002) observed the reason why IFT increases instead of decreasing in this region [72]. Any error in the zone where density is varying strongly with pressure would cause a large deviation in the results. Hebach et al. (2002) did two experiments to conclude that a temperature sensor/thermometer near the pendant drop inside the bulk phase would

produce less error as compared to the one placed in the equipment enclosure. In this work, it was observed that density varies significantly in this region (1500 to 2500 psi at 60°C) as shown in Figure 9.

From 1500 psi (10MPa) to 2500 psi there is a drastic density change in CO<sub>2</sub> at 60°C as shown in Figure 9 and from the phase diagram Figure 8 it can be observed that this point is sensitive to pressure changes.

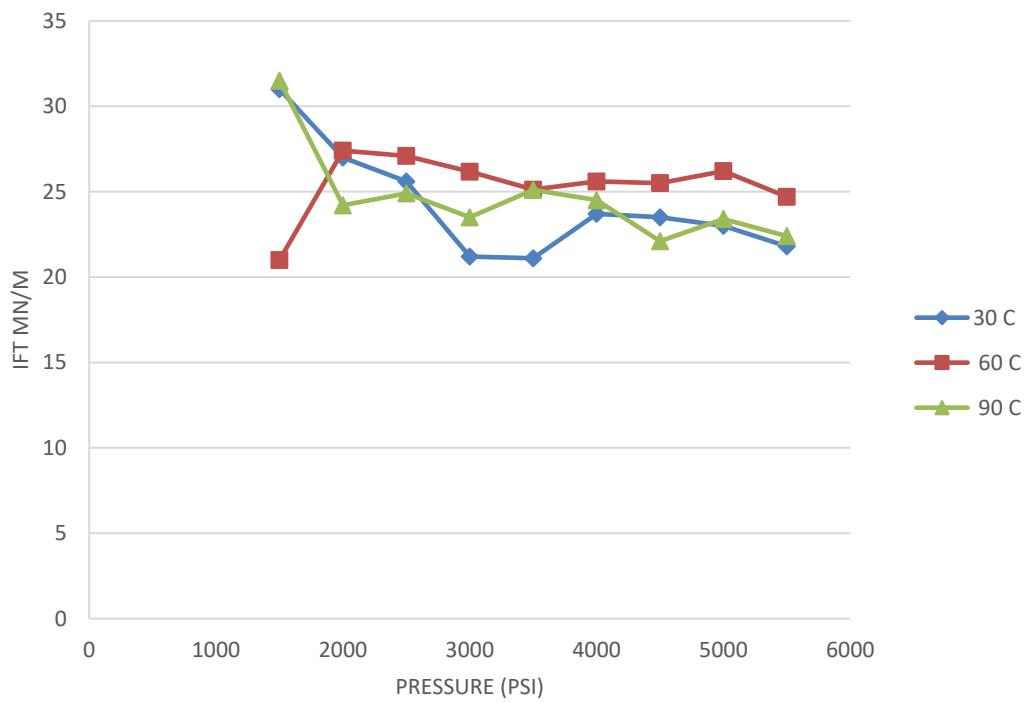

Figure 18: Interfacial Tensions of Brine 1 at different temperatures

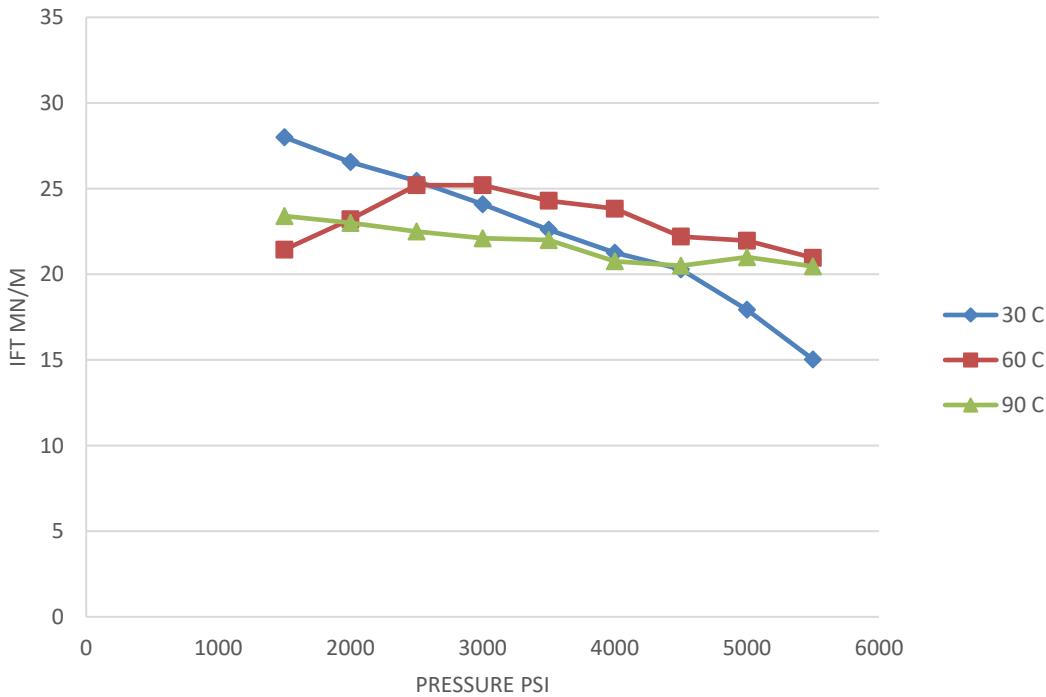

Figure 19: Interfacial Tensions of Brine 2 at different temperatures

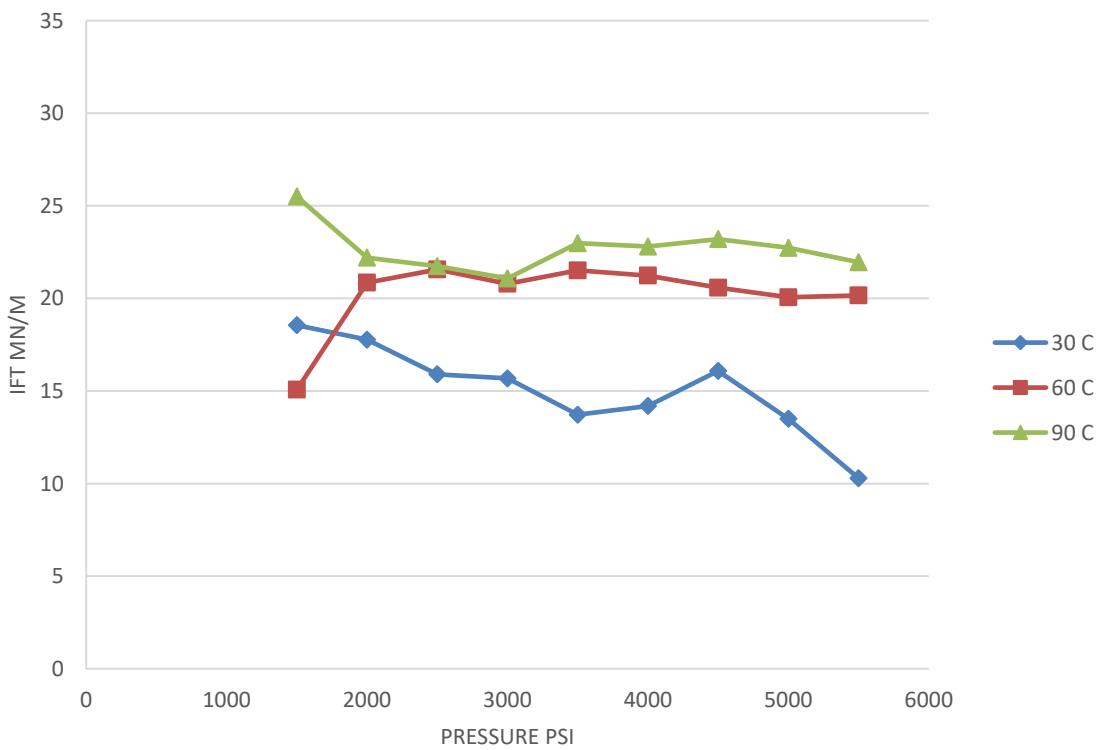

Figure 20: Interfacial Tensions of Brine 3 at different temperatures

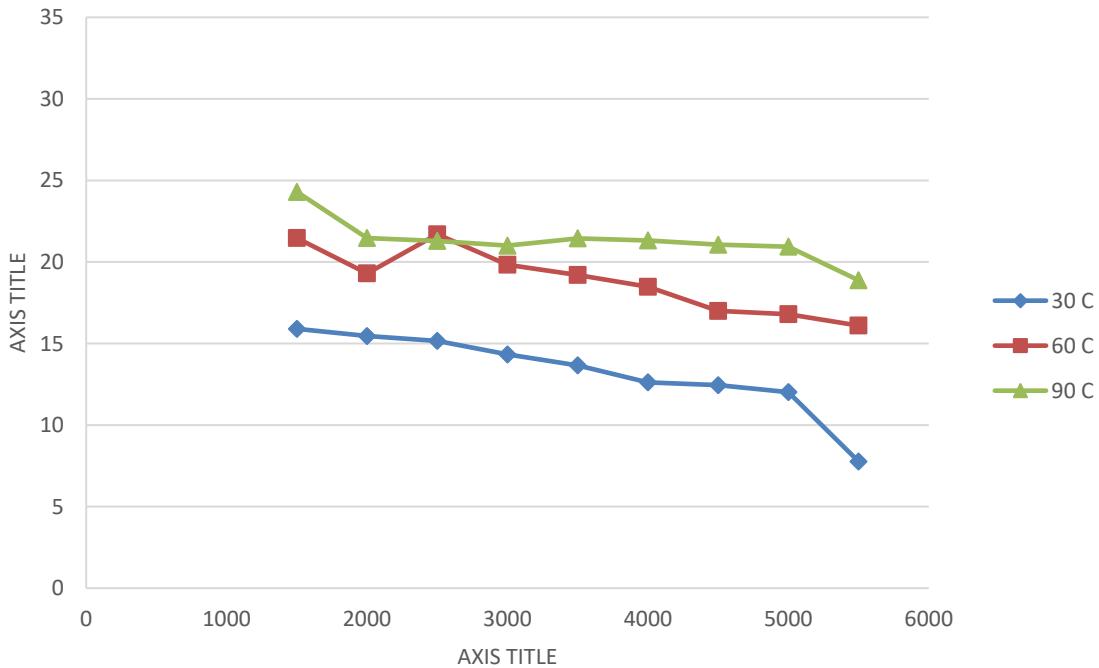

Figure 21: Interfacial Tensions of Brine 4 at different temperatures

Another interesting trend has been observed by Chalbaud et al. (2009) that higher the salinity, lesser is the deviation as shown in Figure 22.

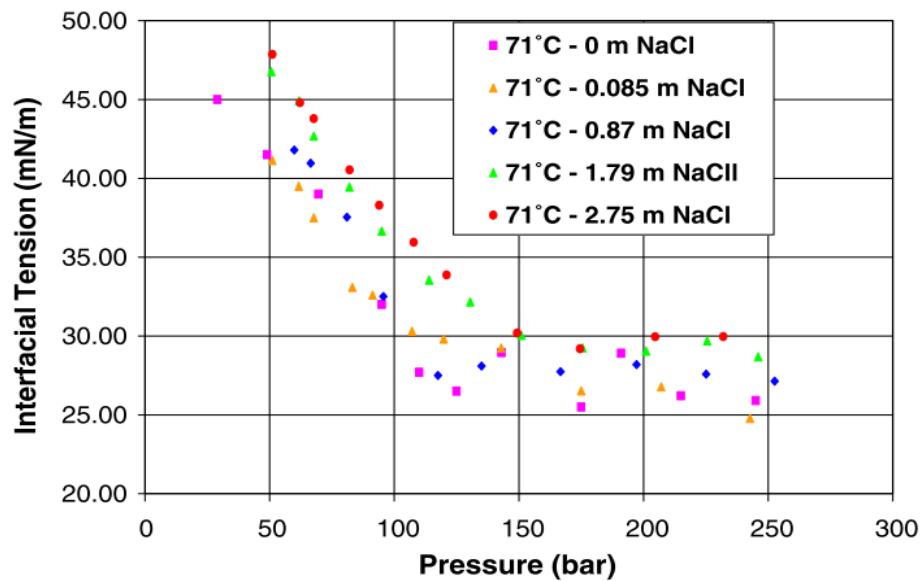

Figure 22: IFT versus Pressure for different conc. of NaCl [73]

This same trend has been observed in this work. For Brine1, the increase is only till 2000 psi whereas for other brines that are in lower salinity the increase is till 2500 psi.

#### **4.2.1.2      Effect of Salinities**

For Figure 23 to Figure 25, at same temperatures and pressures, it is observed that higher the salinity, higher is the interfacial tension. The same trend was observed by (Li et al., 2012) .

From Figure 26 to Figure 28 increase in IFT with salinity does not follow a specific trend of increase. Previously Chalbaud et al. [73] observed that the relation between average IFT increase and salt concentration (Figure 29) is linear in case of simple NaCl brine and similar kind of linear relation is true for many other chlorides. However, they mention that the relation is not linear with higher concentrations of salts and for multi-component brines. Since the brine used in this work is a multi-component brine, therefore no relation can be made between them however trends show that the average IFT increase will increase with increase in brine salinity.

#### **4.2.1.3      Effect of Solubility of Brine and CO<sub>2</sub>**

Spycher et al. (2003) and Spycher (2005) made a literature review and correlation for measurement of CO<sub>2</sub> and water/brine solubility at different temperatures and pressures [74],[75]. They observed that CO<sub>2</sub> solubility in H<sub>2</sub>O decreases with increase in temperature, but increase with increase in pressure for all pressure and temperature ranges. However the solubility of H<sub>2</sub>O in CO<sub>2</sub> increases with both pressure and temperature (Figure 30).

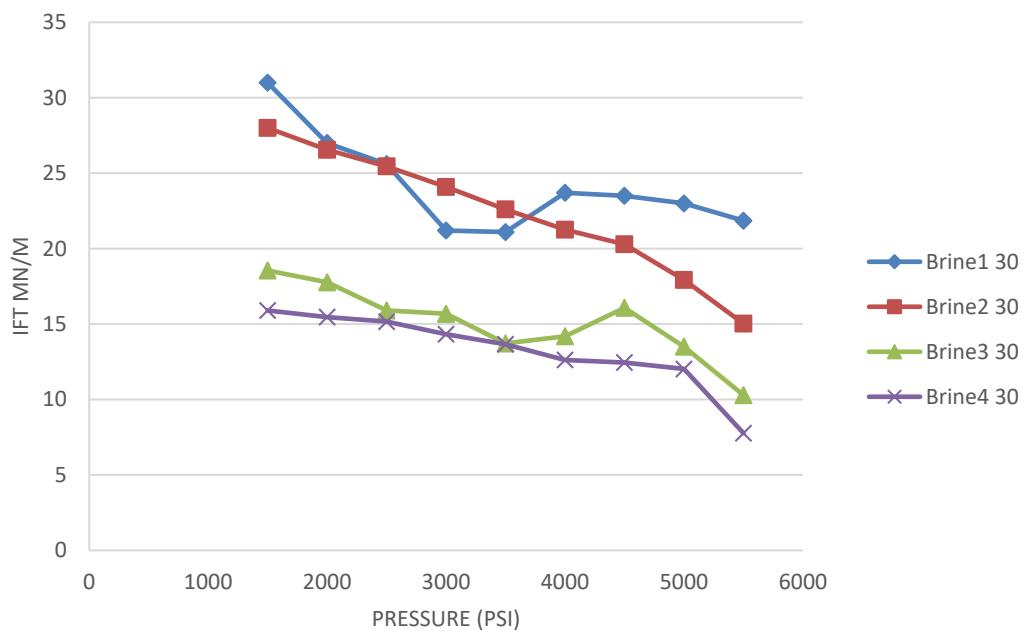

Figure 23: Interfacial Tension of Brines at 30°C

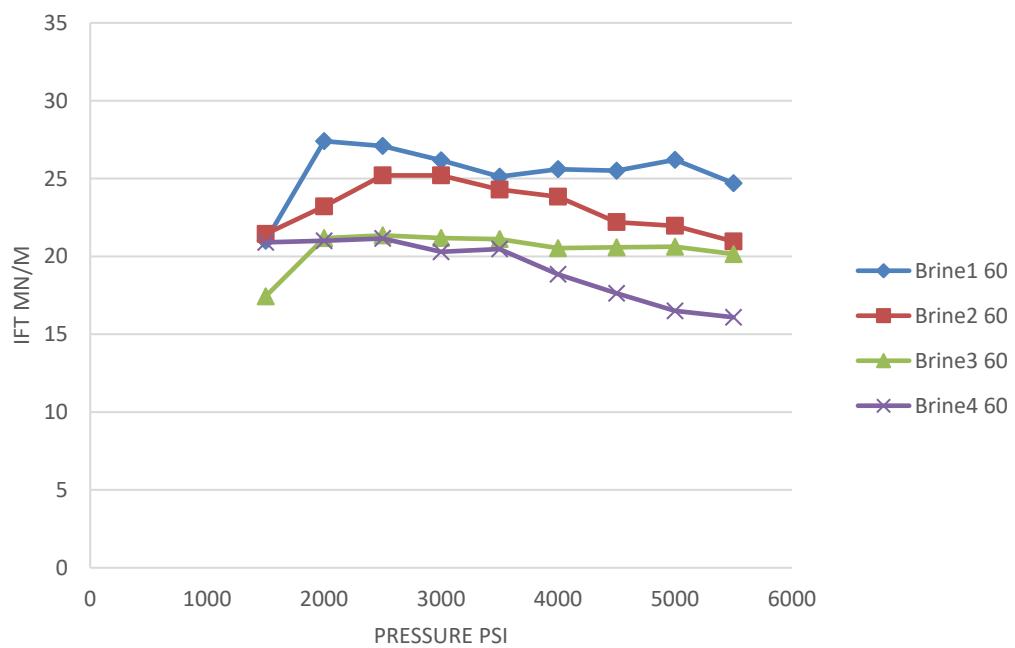

Figure 24: Interfacial Tension of Brines at 60°C

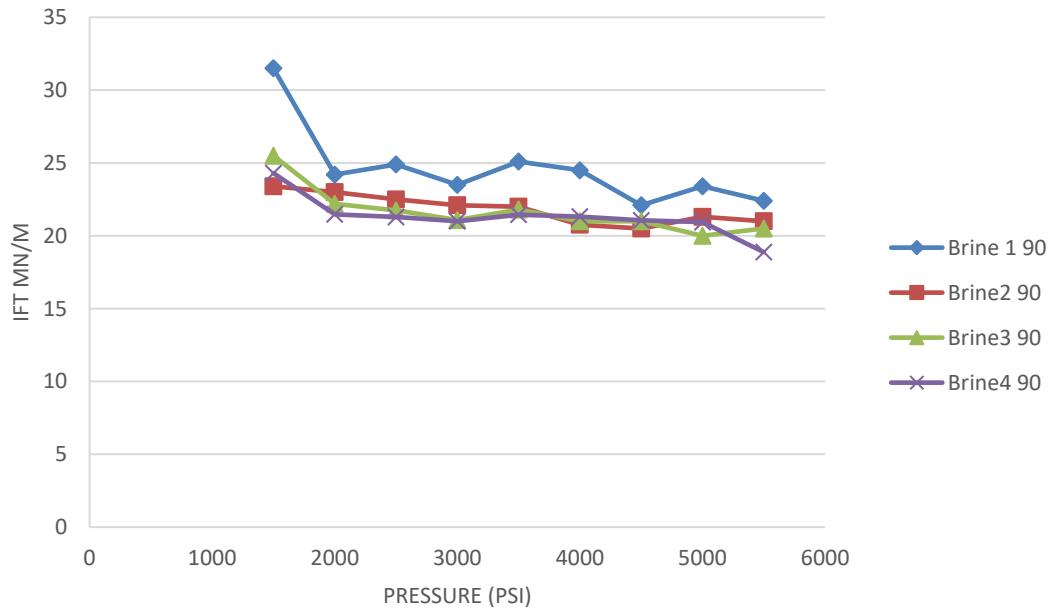

Figure 25: Interfacial Tension of Brines at 90°C

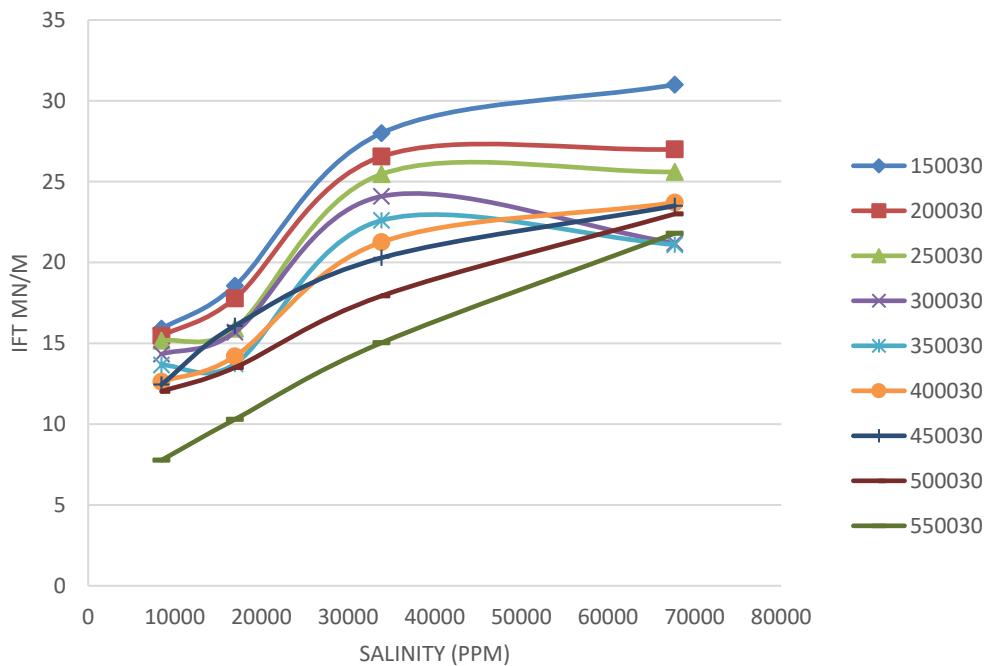

Figure 26: IFT vs Salinities at 30°C and all pressures

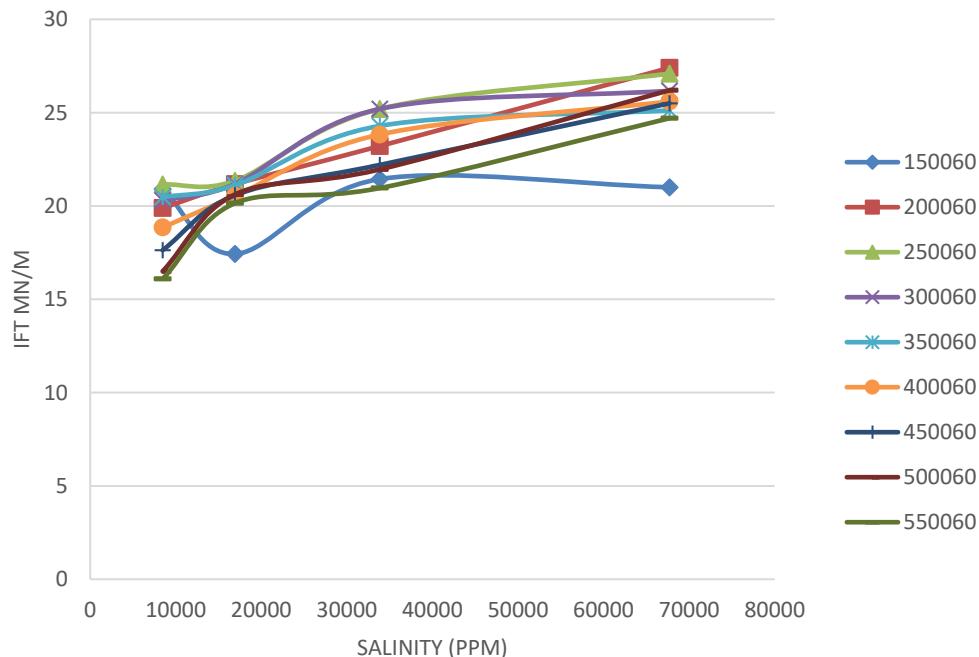

Figure 27: IFT vs Salinities at 60°C and all pressures

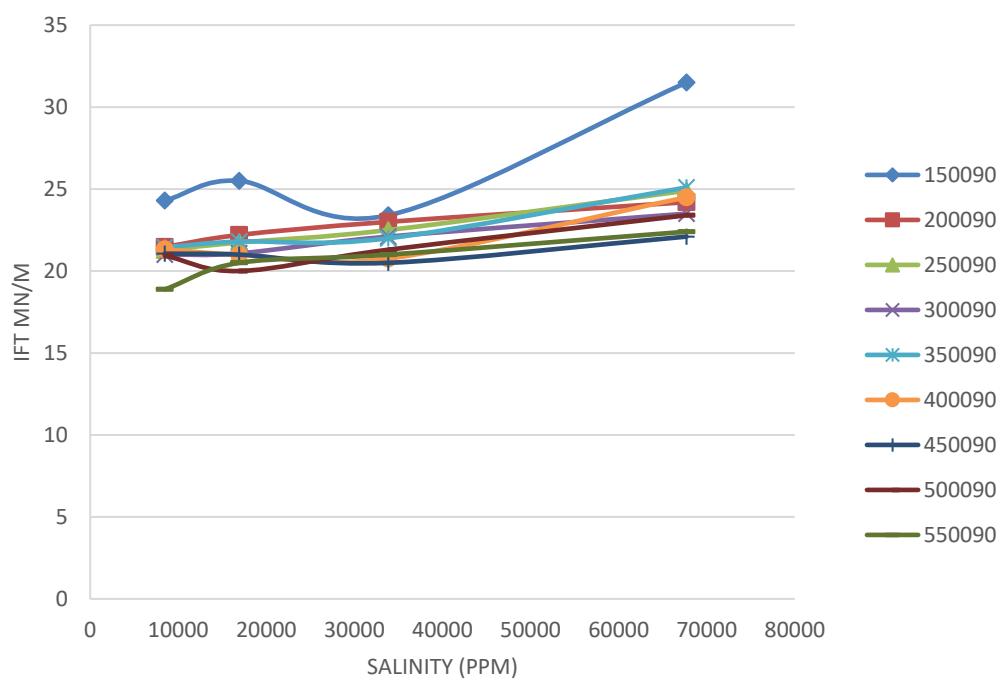

Figure 28: IFT vs Salinities at 90°C and all pressures

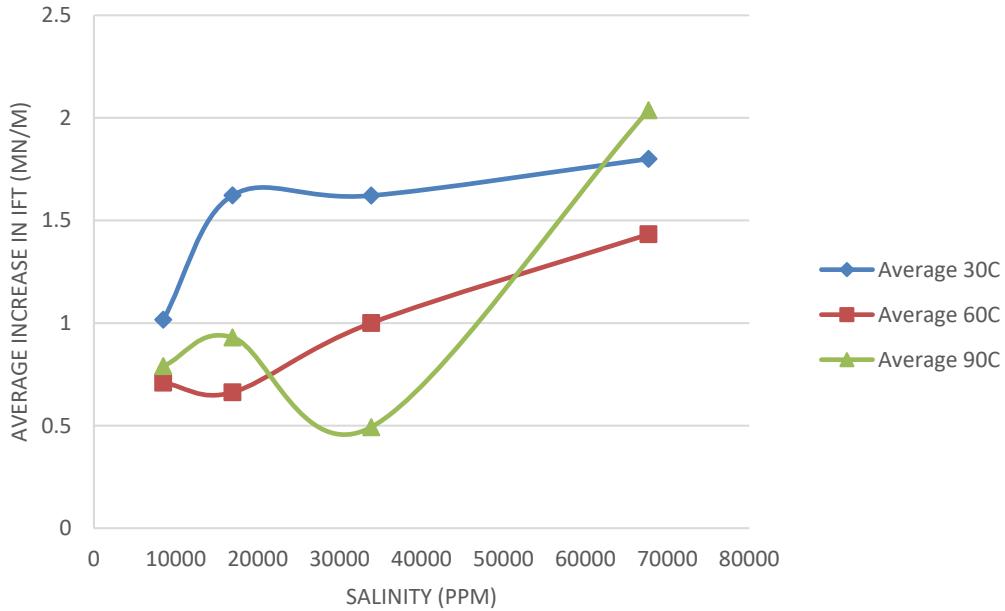

Figure 29: Average IFT increase as function of brine salinity for different T

Yang et al. (2005) explored the relationship between IFT and Solubility of brine and CO<sub>2</sub> [38]. He observed that solubility of CO<sub>2</sub> (using equation of state for real gas) in brine increases as the pressure increases whereas it decreases with increase in temperature and this increase and decrease had a direct influence on IFT. As temperature increases, the brine molecules achieve high kinetic energy to escape the brine interface. Also CO<sub>2</sub> molecules are in high random motion making it easier to diffuse into and out of brine and capture and dissolve brine molecules. The higher is the dissolution of fluids into each other, lesser is the density difference and therefore lesser is the IFT. Yang et al. (2005) explained this dissolution from the work of Teng (1998) that at low temperatures, mass transfer is mostly one-way i.e. CO<sub>2</sub> dissolves into water [38], [76]. However, at high temperatures, there is a two-way mass transfer because CO<sub>2</sub> solubility increase with temperatures. Work of Spycher et al. (2003) also proves the same point [74] . This mass transfer can be observed by swelling and shrinkage of the pendant drop [38].

From Figure 96 to Figure 107, it can be observed that on increasing pressures, for same temperature, the size of the drop increases for all brines. This is due to increase in solubility of CO<sub>2</sub> in brine drop causing the expansion of brine particles in the drop. However, at very high pressure, the drop size either remains constant or decreases a little bit. This is due to the vapor pressure at such high pressure trying to act on the drop surface and therefore decreasing the drop size and also making it difficult to stabilize it for longer times.

Increased salinity of the reservoir brine results in significantly reduced CO<sub>2</sub> solubility [38]. At 30°C, from Figure 96 to Figure 99, Figure 96 is for the Brine with highest salinity and Figure 99 is for brine with lowest salinity. Brine 4 has larger drops and the drop size decreases when salinity is increased for Brine 3, Brine 2 and Brine 1.

However as previously mentioned, not only solubility but vapor pressure and time stabilization is affecting the drop profile, that's why sometimes at high pressure the drop tends to be small.

#### **4.2.1.4      Effect of Brine-CO<sub>2</sub> density difference on IFT**

From Figure 31 it has been observed from our experimental values that IFT depends on density difference. Although here the density difference takes into account the effect of pressure, temperature and salinity. Nevertheless, density difference is not the only parameter to predict the IFT here and in Figure 32 it has been shown that at same density difference IFTs can be obtained and that this is mainly the consequence of salinity.

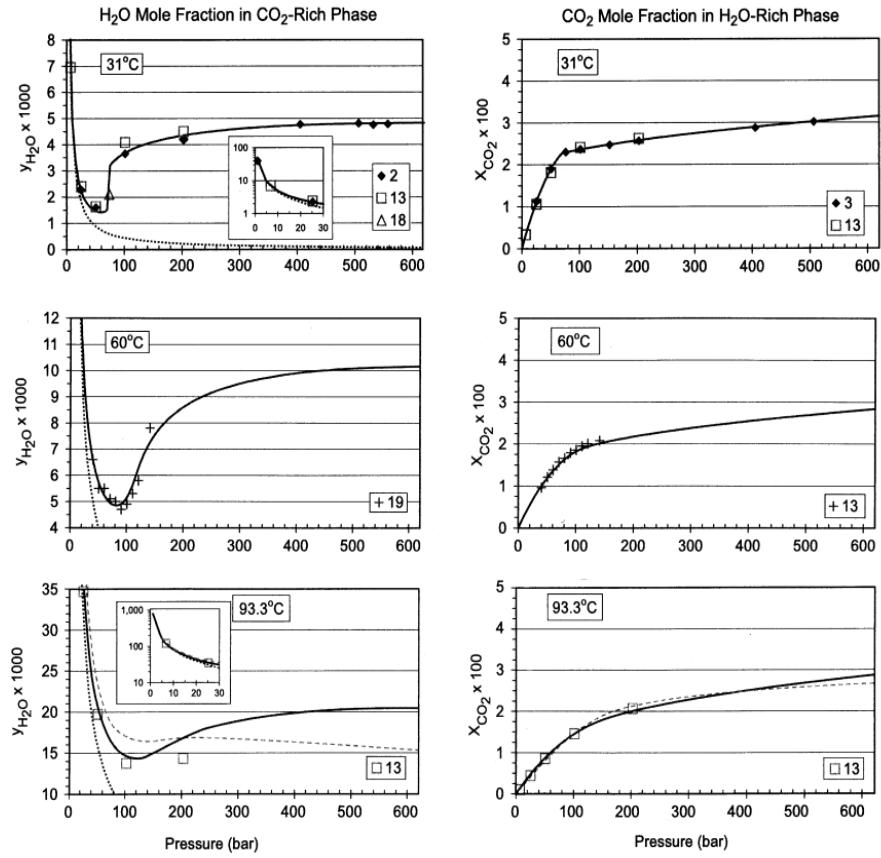

Figure 30: (Spycher et al., 2003) Solubility of  $\text{CO}_2$  and water

However, the density difference variation follows the same trend making it easier to predict the behavior of IFT with density difference.

Similar results were plotted by [73] however they did not plot at points where density difference is less than 0.2 g/ml. IFT increases linearly till density difference of 0.2 g/ml and forms a plateau (or a region of less increase) at certain region of density difference and as the density difference increases further, the IFT slope changes again making it almost linear increase.

#### 4.2.1.5 Change of Brine IFT with time

Many authors have reported the an experimental trend of change in IFT in their work [22], [37], [38], [70], [72], [73], [77] similar to the one shown in Figure 33.

Once the drop was generated from the capillary needle, it was maintained for at least 10 minutes in this work for brine and CO<sub>2</sub> system. Initially the drop comes into contact with the bulk fluid (CO<sub>2</sub>) and, since both fluids are unsaturated, the drop is initially enlarged due to intake of CO<sub>2</sub>. Later the mass transfer of water into CO<sub>2</sub> takes place. Due to this dissolution IFT decreases till a point of equilibrium for some time.

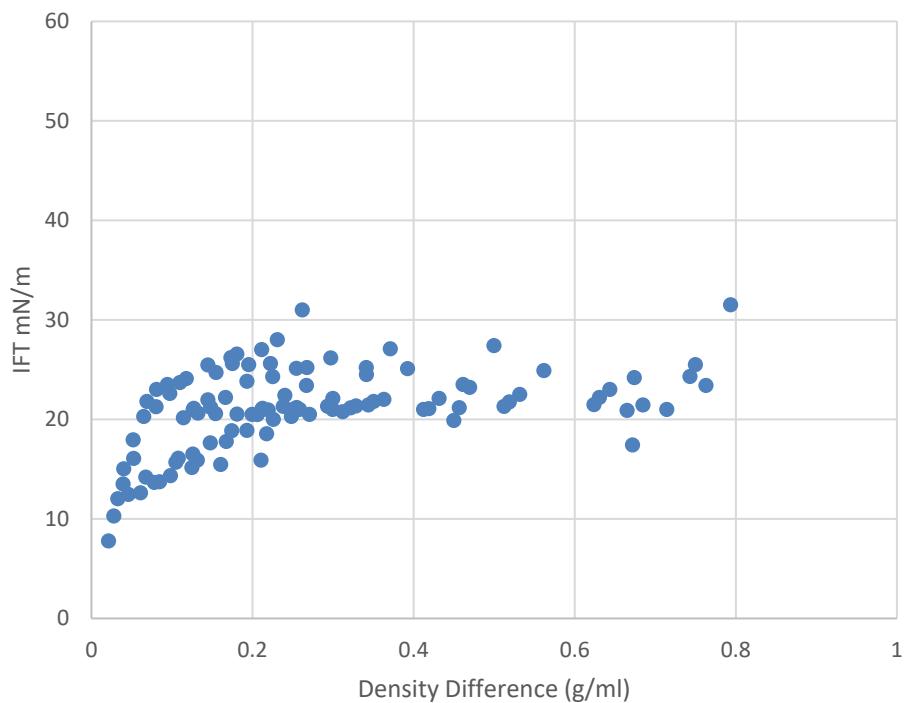

Figure 31: Variation of IFT with Brine-CO<sub>2</sub> density difference

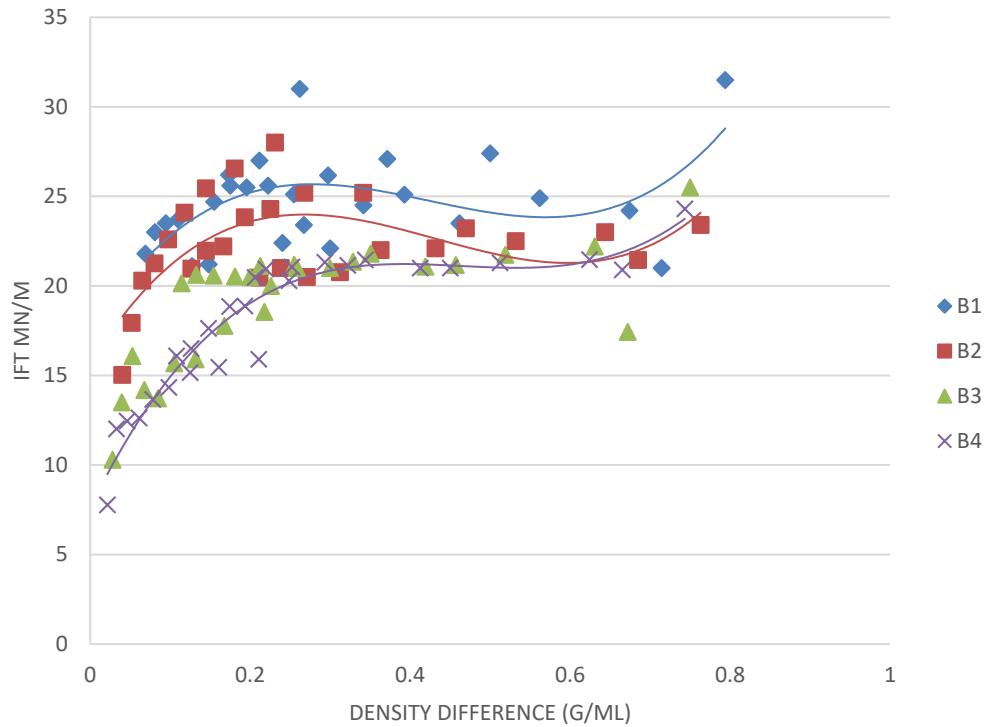

Figure 32: Trends of IFT with density difference

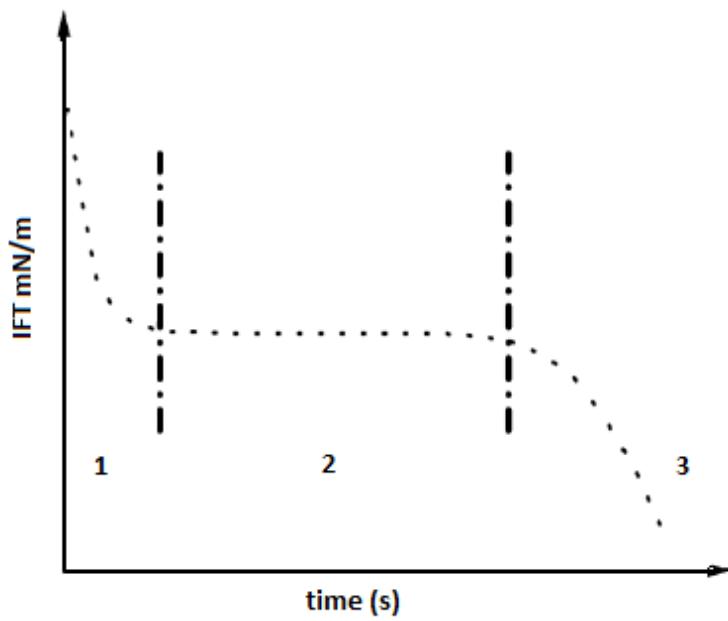

Figure 33: Time dependence of IFT

This 2<sup>nd</sup> region is the best time to measure the IFT values. IFT continues to decrease with time afterwards because the vapor pressure above a positively curved surface is higher

than that above a flat surface. Therefore, it is difficult for the drop to maintain equilibrium for longer time and as a consequence it becomes smaller with time and therefore the volume of the drop changes. While the dia of the needle remains constant, the drop shape changes and thereby causing error in IFT calculation below a certain drop volume.

For this work, IFT variation with time has been shown in Appendix D.

#### **4.2.1.6 Determination of Minimum Miscibility Pressure**

If the difference between the intermolecular forces is small, the interfacial tension between the two phases is small and vice versa the interfacial tension between the two phases is large. Only if the intermolecular forces operating with two phases are equal, the molecules on the interface between the two phases are under balance of forces. As a result the interface between the two phases disappears, the value of interfacial tension between the two phases is zero and the two phases are miscible [78].

Minimum miscibility pressure is defined as the pressure at which no drop for IFT can be formed and IFT is therefore zero. This can be estimated by extrapolating the decreasing lines, on plot of pressure vs IFT, till x-intercept i.e. where y-axis value (IFT) becomes zero.

Table 10: Minimum Miscibility pressures in psi of brines

Temperatures	30	60	90
	MMP (psi)		
<b>Brine 1</b>	17707	46990	21204
<b>Brine 2</b>	10986	19640	30552
<b>Brine 3</b>	12848	55722	27702
<b>Brine 4</b>	11231	12685	30040

The minimum miscibility pressures for all four brines at each temperature have been given in Table 10. Since at high temperatures, the solubility of CO<sub>2</sub> in H<sub>2</sub>O decreases it becomes difficult to make them miscible and very high pressure is required. There is a need for more points at high pressures to predict the effect of salinity on MMP using the plot of IFT vs Pressure.

#### **4.2.2 Brine-Surfactant Solutions (BSS) as drop fluids and CO<sub>2</sub> as Bulk Fluid**

Since the lowest IFT was given by Brine4 (i.e. the brine with lowest salinity), therefore this brine was selected for next step of system for comparison of three different surfactants.

##### **4.2.2.1 Effect of Temperature and Pressure**

From Figure 34 to Figure 36 it can be seen that IFT increases with increase in temperature and decreases with increase in pressure. This trend is continuous for all surfactants except for Alfoterra at 90°C. Alfoterra can give ultra-low IFT at low temperatures (less than 60°C) and low salinity of NaCl [63]. 40,000 ppm is the minimum salinity defined by the manufacturer. Alcohol ether sulfate surfactants have poor hydrolytic stability at high temperatures (above 65°C) and therefore decompose [79]. However addition of co-surfactants or alkali (sodium carbonate) in low concentration can increase the stability of this surfactant till 120°C [79], [80].

In this work, brine consists of several components and therefore the effect of sodium carbonate cannot be separated. Also salinity is 8464 ppm but sodium carbonate concentration is quite high. Therefore, the surfactant inside the brine drop is decomposing at such a high temperature and pressures. BSS1 couldn't show any ultra-low IFT however

IFT is still lesser than the brine without surfactant. IFT initially decreases with increase in pressure but after a certain point it continues to increase with pressure. Similar kind of increasing IFT has been reported when the surfactant is used in highly saline system by [63]. Another cause of this behavior could be the presence of divalent cations in the brine which are a great threat to aqueous solubility and cause precipitation with the ether sulfate surfactant [81]. All of the above factors could also be the reason for no-ultra low IFT, however IFT is still quite low.

IFT of Armovis EHS also increases with increase in temperature. [65] has also used a viscoelastic surfactant for lowering the IFT and observed a similar kind of increase in IFT with increase in temperature. Effect of pressure on IFT has not been observed before in the

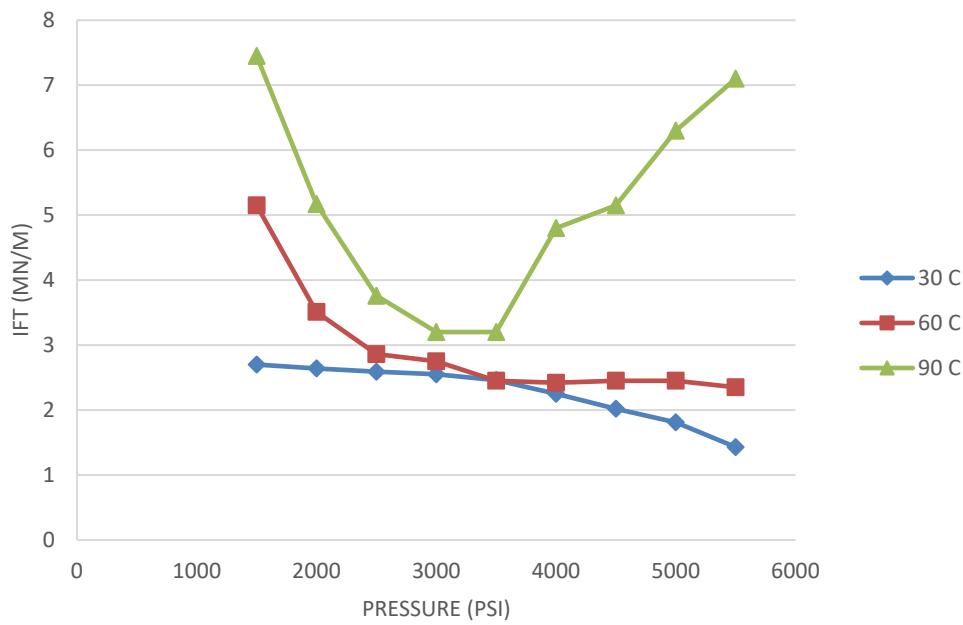

Figure 34: Interfacial tensions of BSS1 at different temperatures

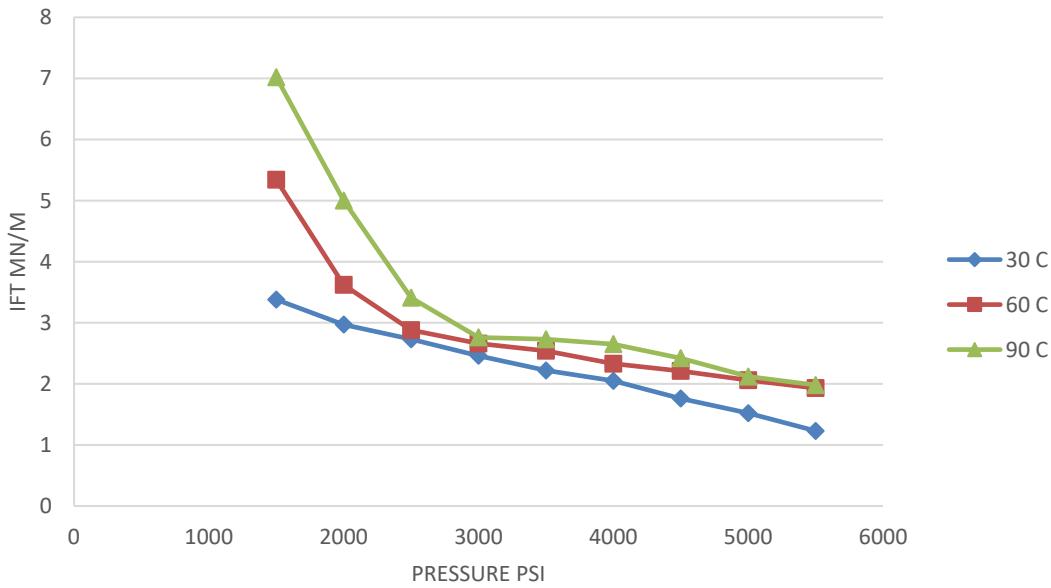

Figure 35: Interfacial tensions of BSS2 at different temperatures

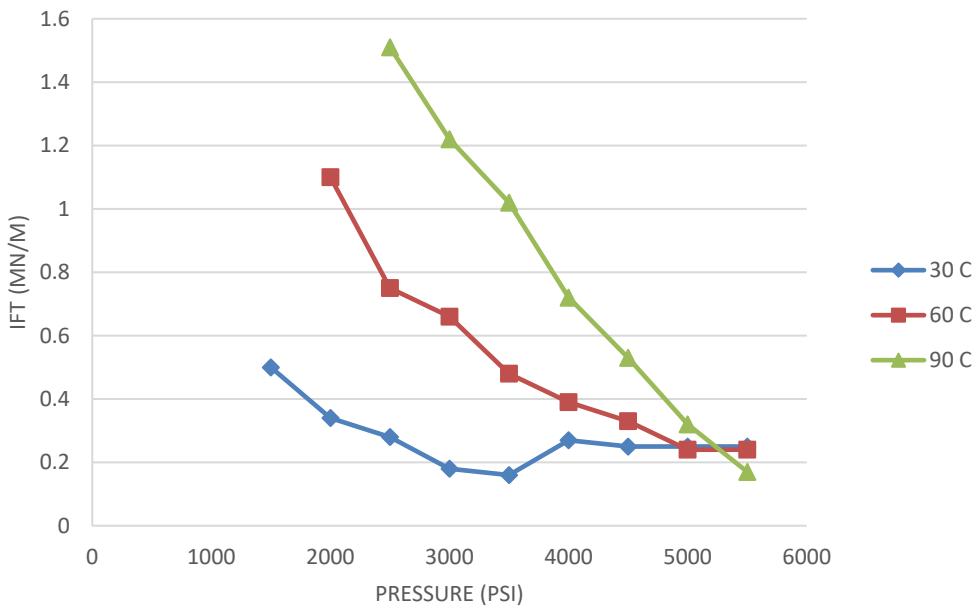

Figure 36: Interfacial tensions of BSS3 at different temperatures

literature. IFT decreases with increase in pressure at each temperature and this behavior is attributed to solubility.

For FS-50 (fluorosurfactant) ultra-low IFTs have been achieved. This makes it the best surfactant for this system and conditions. Also due to its lipophobicity, it is oil repellent and can be used to decrease IFT and wettability with oil systems.

IFT decreases with increase in pressure but increase with increase in temperature. However, at pressures 5000 and above, IFT becomes almost independent of pressures and temperatures. This point is the limit of solubility of CO<sub>2</sub> and Brine. From Figure 108 to Figure 116 it can be observed that drop becomes hazy with increase in pressure at all temperatures. This is due to increased solubility of CO<sub>2</sub> in brine and making emulsions with surfactant and at high pressure, no further emulsification is possible therefore IFT becomes constant and independent of pressure and temperature.

#### **4.2.2.2 Effect of Surfactant type**

From Figure 37 to Figure 39 it can be observed that IFT has been reduced to a very less value because of the use of surfactants as compared to simple brine without surfactants. This is because generally CO<sub>2</sub> is a poor solvent for both lipophilic and hydrophilic solutes [82] and surfactants can disperse these lipophilic or hydrophilic phases (which may both be considered CO<sub>2</sub>-phobic) into supercritical CO<sub>2</sub> in the form of micro-emulsion, emulsions and micelles [83] [39].

Because of very less polarizability and dielectric constants of CO<sub>2</sub>, any CO<sub>2</sub>-philic type of functional group in a surfactant will provide low energy-density. The ones with low cohesive densities and surface tensions are the most soluble [83]. Fluorosurfactants have given the ultra-low IFT because of their best suitability to the system. Although its boiling point is 82°C for a pure surfactant, but when mixed as 0.15% in Brine it

performed very well at 90°C. It has low surface tension of pure surfactant. Also its function is not affected by salinity.

#### **4.2.2.3 Solubility of BSS and CO<sub>2</sub>**

Although what exactly governs solubility in CO<sub>2</sub> is not entirely clear but researchers have investigated the design of so-called “CO<sub>2</sub>-philic” surfactants that are soluble in CO<sub>2</sub> at moderate temperatures. K. Consan and R. Smith are notable authors who investigated almost 130 surfactants with CO<sub>2</sub> at 50°C and pressures from 1500psi to 7250 psi [84]. They observed that commercially available surfactants exhibit low solubility in CO<sub>2</sub> however some fluorinated surfactants appreciably dissolve in CO<sub>2</sub>.

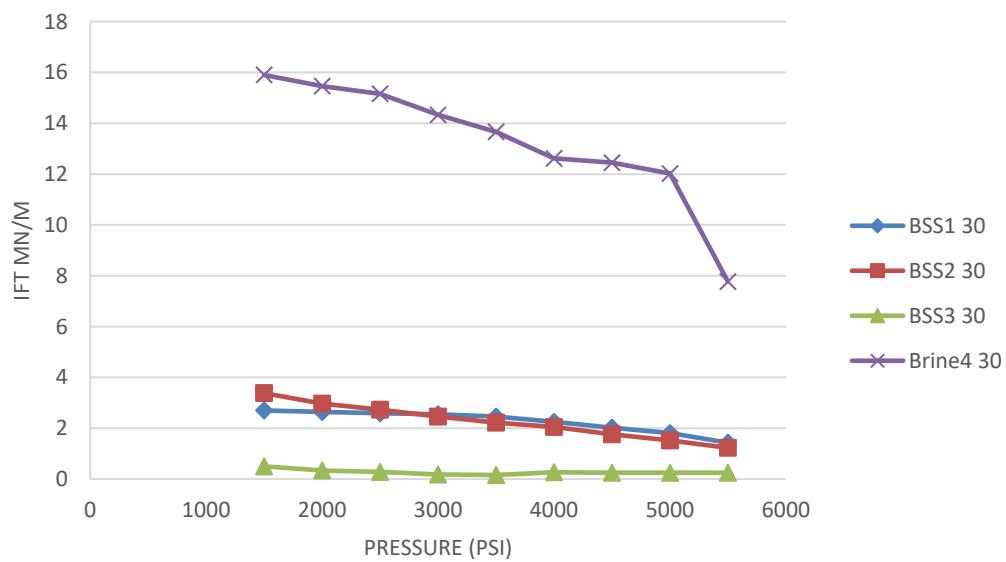

Figure 37: Interfacial tensions of Brine-Surfactant Solutions at 30°C

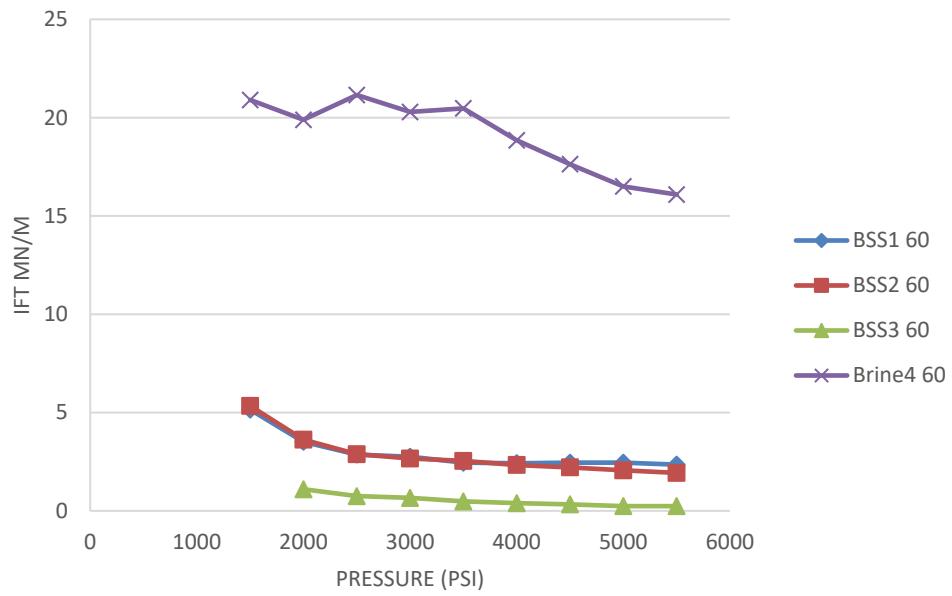

Figure 38: Interfacial tensions of Brine-Surfactant Solutions at 90°C

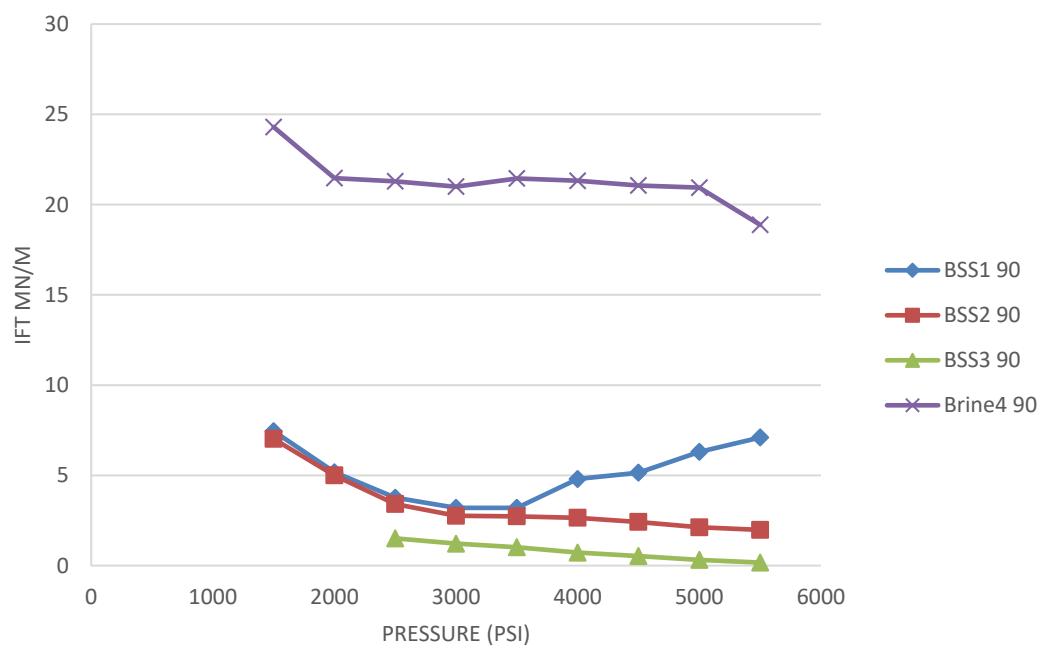

Figure 39: Interfacial tensions of Brine-Surfactant Solutions at 90°C

This work proves the same point that ultra-low IFT values have been obtained with fluorosurfactant FS-50 Solution.

If a substance is partially soluble, the formation of fog upon slight decompression is taken as evidence for some degree of solubility [84]. From Figure 108 to Figure 116, increase in pressure causes an increase in fog inside the bubble which explains the increase in solubility with pressure. Increase in solubility with increase in pressure is similar to the system of Brine-CO<sub>2</sub> mentioned earlier.

#### **4.2.2.4 Effect of BSS-CO<sub>2</sub> density difference on IFT**

From Figure 40 we can deduce that incase of BSS, IFT is depending on density difference making a trend similar to Figure 32 except for a few outliers.

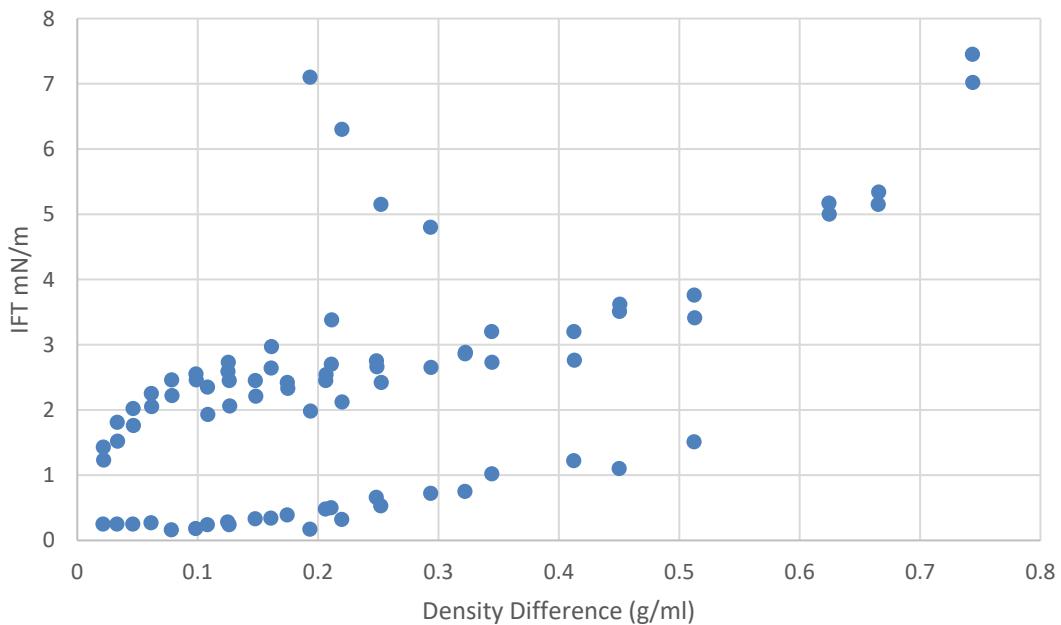

Figure 40: Trends of IFT with density difference for BSS

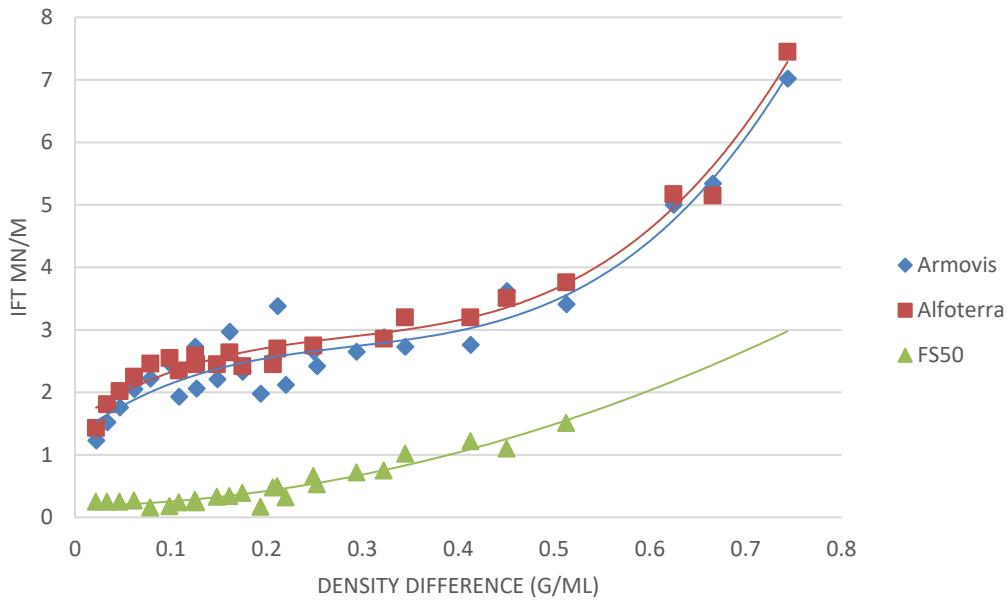

Figure 41: Effect of Density Difference on IFT for BSS

Since the outliers were due to decomposition of surfactant, we have excluded them in Figure 41. Since Armovis and Alfoterra are of similar chemical nature, they make a similar trend w.r.t to density difference. For density difference less than 0.2, there is a rapid linear increase in IFT with respect to density difference. Up till 0.6 the increase is gradual and afterwards the increase is linear again. This is the same trend that was observed for case of simple Brine-CO<sub>2</sub> systems (Figure 32). However, FS50 is a fluorosurfactant and the trend was found to be linear.

#### 4.2.2.5 Determination of Minimum Miscibility Pressure

Minimum miscibility pressure is defined as the pressure at which no drop for IFT can be formed and IFT is therefore zero. This can be estimated by extrapolating the decreasing lines, on plot of pressure vs IFT, till x-intercept i.e. where y-axis value (IFT) becomes zero

However, in case of surfactant solutions, MMP cannot be properly determined because the surfactant is present in the system and a small change in pressure and temperature can have large influence on density and thus the solvent strength of CO<sub>2</sub> and BSS. Emulsion formation occurs inside the system which will be explained in detail in the next part of experiments with oil and the system undergoes a phase inversion and surfactant preference for either phase changes due to which IFT starts increasing instead of decreasing [39] which makes it impossible to predict the miscibility pressure.

#### **4.2.2.6 Change of BSS-CO<sub>2</sub> IFT with time**

The trend similar to Figure 33 for Brine holds for BSS-CO<sub>2</sub> system. Alfoterra takes more time to stabilize as compared to other two Brine-Surfactant solutions as shown in Appendix D. This is because Alfoterra is a fluid with density and viscosity higher than other two surfactants depicting strong intermolecular forces thereby taking more time to come to equilibrium.

#### **4.2.3 Oils as drop fluids and CO<sub>2</sub> as a bulk fluid in the presence of BSS3**

Since the lowest IFT has been shown by BSS3, our next experiments were carried out on this Brine-surfactant solution.

As mentioned in the previous chapter that some BSS3 drops (approx. 0.1 ml) were dropped inside the cell and CO<sub>2</sub> was filled and allowed to stabilize for some time at the desired temperature and pressure. Five oils were used one by one as drop fluids at one

temperature ( $60^{\circ}\text{C}$ ) and nine different pressures. Their results have been shown in Figure 42 to Error! Reference source not found..

#### 4.2.3.1 Effect of Temperature and Pressure

In these experiments, at some pressures, the density of the bulk fluid ( $\text{CO}_2$ ) became heavier than the density of drop fluid (oil) therefore the configuration of IFT equipment had to be inverted i.e. inverse pendant drop.

According to the literature and work done by Li et al. in 2012, for simple systems without surfactant, Interfacial tension decreases with increase in pressure [31].

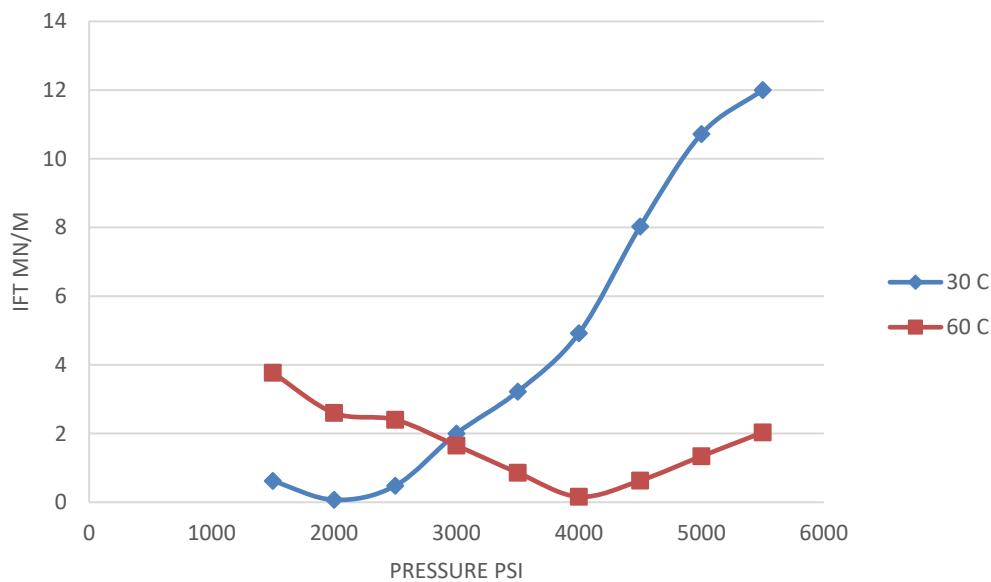

Figure 42: Crude oil 1 as a drop fluid at two temperatures

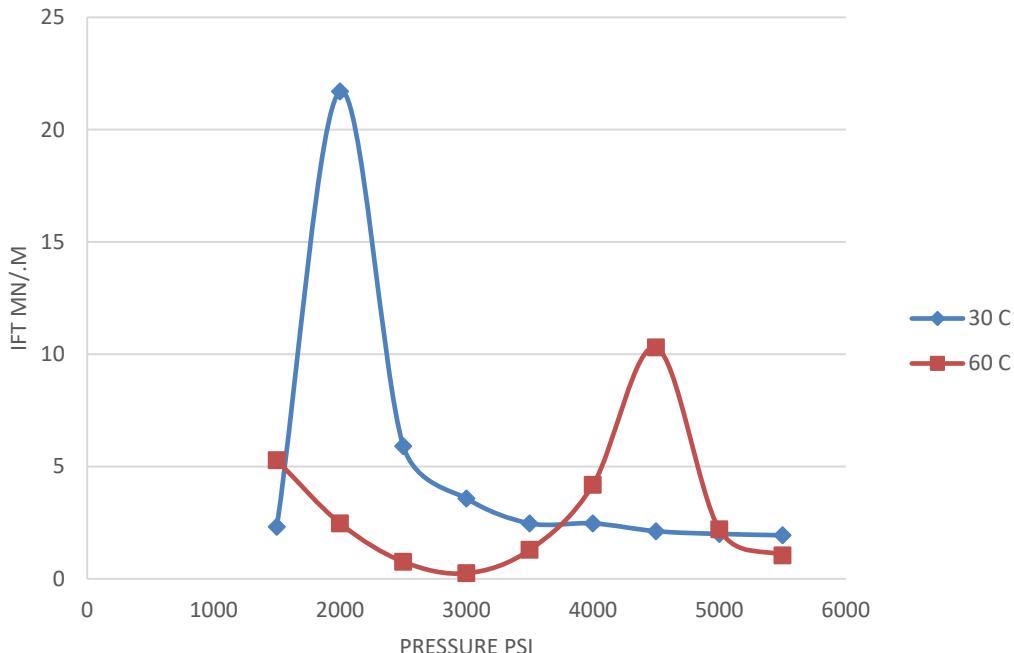

Figure 43: Interfacial tensions of Squalane at two temperatures

However the results in this work (Figure 42 and Figure 43) show that for Crude oil 1 Crude Oil IFT decreases till 2000 but then continues to increase with pressure. However, at 60°C it decreases till 3500 psi and then increases. For Squalane which is a single component model oil, the IFT continues to decrease with pressure till 3000 psi at 60°C. After 3000 till 4500, an increase in IFT is observed. After 3000 psi, CO<sub>2</sub> becomes denser than squalane however still the falls downwards until 4000 psi. At 4500 psi, the configuration of the equipment was changed and the drop was generated which resulted in very high IFT.

At 30°C, only one experiment at 1500 psi could be performed in pendent drop configuration. Later all the values were taken with inverse pendent drop configuration

because of the density inversion, a high value of IFT was measured, just like the one at 4500psi at 60°C. Afterwards, IFT keeps decreasing with pressure.

The above results can be explained as the effect of formation of emulsion/micro-emulsion inside the cell due to surfactant. Shear causes oil fingers in water and water fingers in oil at the interface of which molecules of a surfactant are adsorbed. These fingers break up forming Oil/water and water/oil emulsions [40]. This same phenomenon is valid for supercritical CO<sub>2</sub> and Oil in presence of surfactants. [85] investigated the formation of emulsions, micro-emulsion, phase behavior and curvature for an oil/water micro-emulsion by plotting it on log of IFT. Da Rocha in 1999 summarized this kind of behavior for CO<sub>2</sub>, water and surfactant systems in Figure 44 [39].

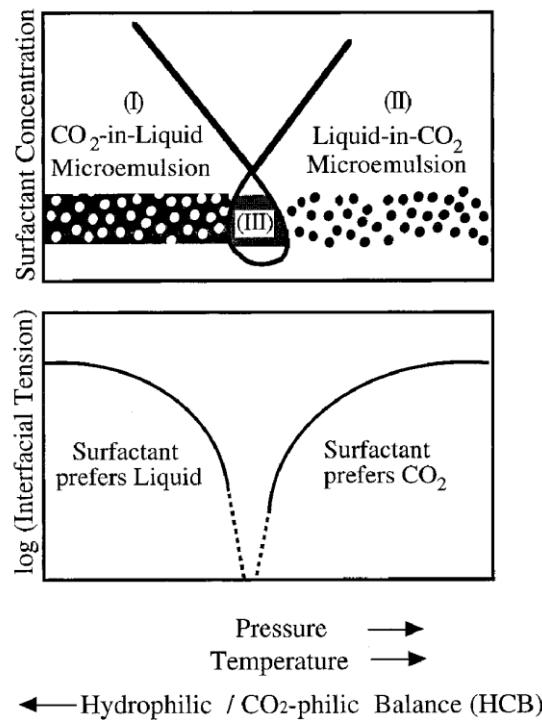

Figure 44: [39] Phase behavior in system of CO<sub>2</sub>, H<sub>2</sub>O and surfactant

Log (IFT) plots for Oil-CO<sub>2</sub> IFTs, in the presence of Brine-surfactant solution, have been shown from Figure 45 to Figure 48

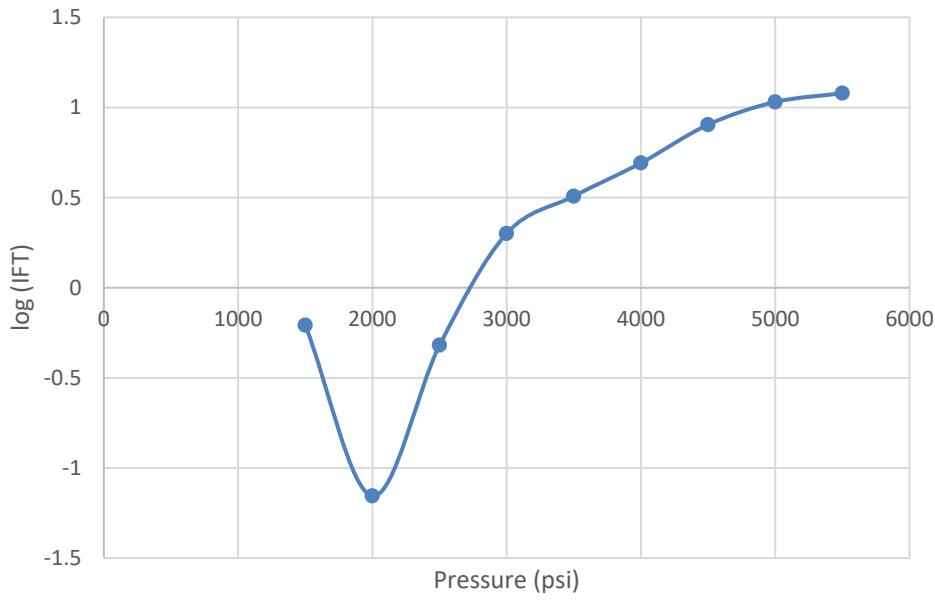

Figure 45: Log (IFT) vs Pressure for Crude oil 1 at 30°C

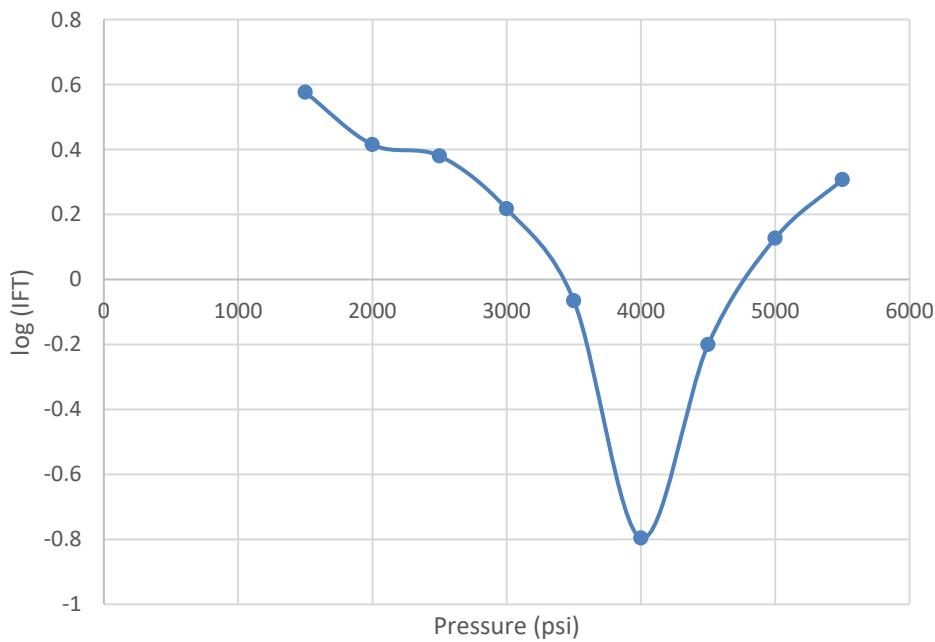

Figure 46: Log (IFT) vs Pressure for Crude oil 1 at 60°C

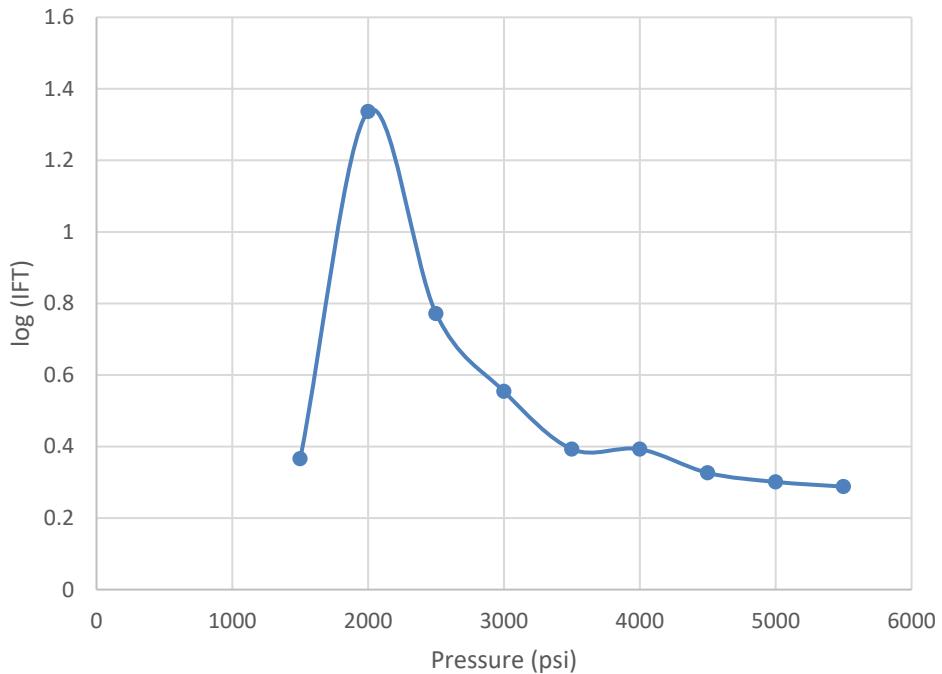

Figure 47: Log (IFT) vs Pressure for Squalane at 30°C

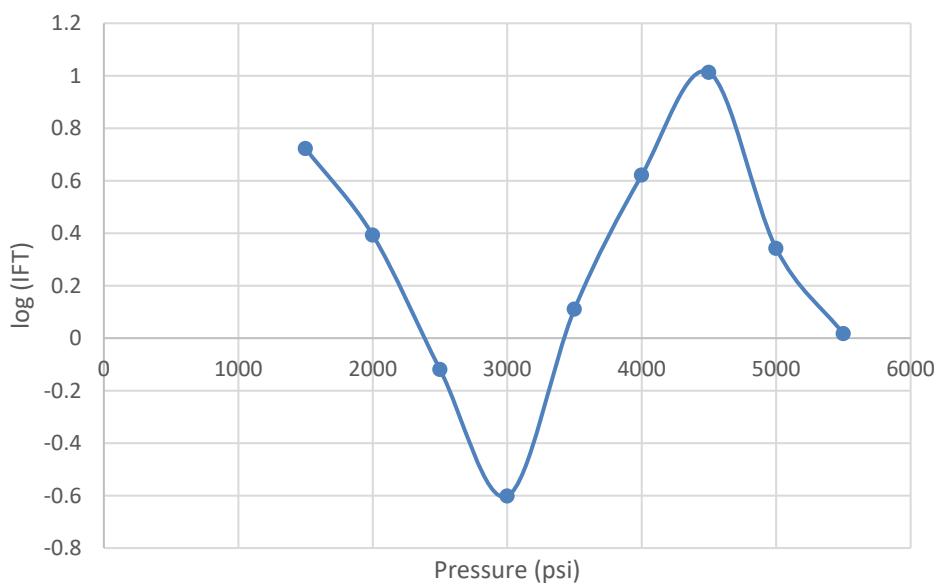

Figure 48: Log (IFT) vs Pressure for Squalane at 60°C

The phase which contains most of the surfactant become the continuous phase while the other becomes dispersed phase for both micro emulsions and macro emulsions [40]. When the system is balanced w.r.t partitioning of the surfactant between both the phases, a minimum in IFT value is observed. This point is called phase inversion point and a change in any temperature, pressure (for compressible fluids) or hydrophilicity/hydrophobicity ratio (or in this case hydrophilic/CO<sub>2</sub>-philic ratio) will cause the surfactant to migrate towards one of the phases [86].

This phase then becomes the external (continuous) phase [40][39]. During emulsification the droplets are deformed and/or broken. Then the surfactant approaches and adsorbs onto deformed/broken newly formed droplets. The surfactant lowers the IFT and thus the Laplace pressure, thereby facilitating droplet breakup by reducing the energy required to break/deform the interface of the droplet [87].

Consider for Crude oil 1, increase in pressure is causing a shift from surfactant's preference for Oil (CO<sub>2</sub>-in-liquid micro-emulsion) to surfactants preference for CO<sub>2</sub> (liquid-in- CO<sub>2</sub> micro-emulsion). However, the brine is also being emulsified inside CO<sub>2</sub> which is indicated by the fog inside the cell making it difficult to view. However, this Brine emulsion is not completely stable and disappears in 5 to 8 hours and the system was kept in this state prior to the first reading at 1500 psi for each of the two temperatures.

From Figure 49 at high temperature, the point of phase inversion/HCB (Hydrophilic-CO<sub>2</sub> philic Balance) point is delayed. This is in accordance with literature and previous

discussion that a small change in temperature can have a large influence on solvent strength of supercritical CO<sub>2</sub>

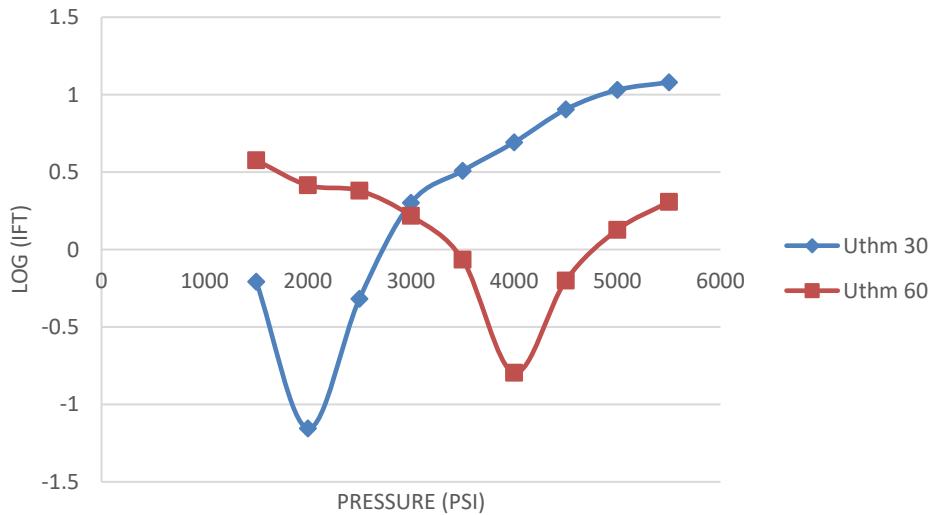

Figure 49: Effect of Temperature on Crude oil 1 for Log (IFT) vs pressure

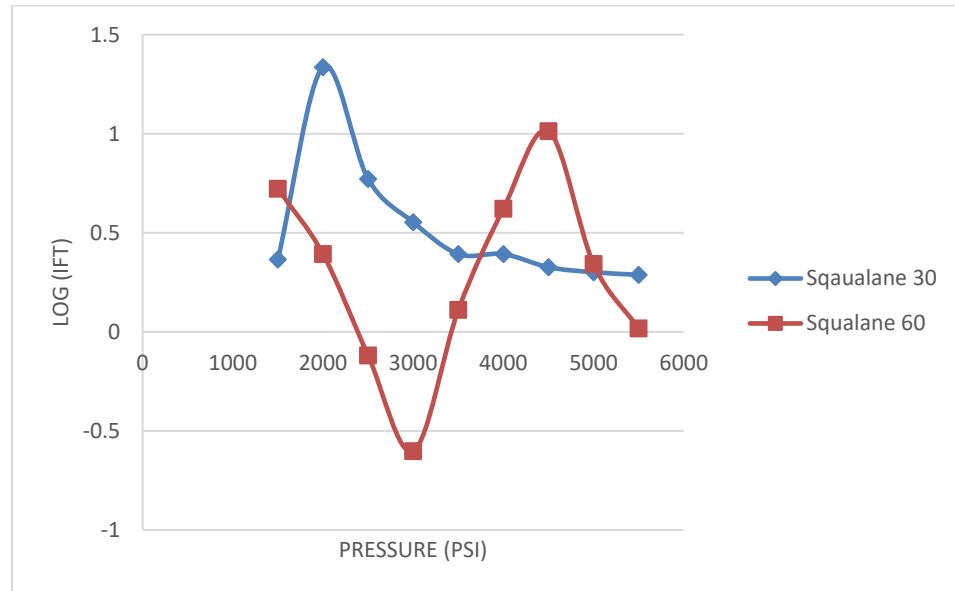

Figure 50: Effect of Temperature on Squalane for Log (IFT) vs pressure

. Since phase density has a big role in surfactant preference [39][86], increase in temperature is causing a change in density of the phase due to which surfactant changes its preference. At high temperature, the CO<sub>2</sub>-in-liquid micro-emulsion is stronger for

quite higher pressures and phase inversion pressure (PIP) changes from 2000 psi to 4000 psi.

For Squalane, considering both Figure 47 and Figure 48, at 2000 psi, 30°C and 4500 psi, 60°C, the density configuration of the system has to be changed because at these pressure and temperature conditions, CO<sub>2</sub> became denser than and the Squalane drop rose upwards (Figure 117 and Figure 119). On these conditions, the IFT again starts to decrease but this time, no oil-in-CO<sub>2</sub> emulsion was formed in the system judging from the semi-log plot since the curvature is not following the decreasing downward slope. Rather the decrease is due to increase in pressure that causes an increase in the solubility of CO<sub>2</sub> and also due to the role of intermolecular forces. However the system still remained foggy (Figure 117 and Figure 119) which means that brine was being emulsified in CO<sub>2</sub> at 30°C. But at 60°C system remained clear.

The experiments could not be performed at 90°C because, at this temperature, emulsification of Brine in CO<sub>2</sub> was quite high making the glass of the cell foggy therefore making it difficult to see the drop through the camera. Also some foam along with mist would accumulate on the glass. Only results of 30°C and 60°C could be shown in this work.

#### **4.2.3.2      Effect of types of Oils**

From the trends it is clear that we cannot generalize the outcome of IFT and neither can we consider one oil to be better candidate than the other. One is a crude oil, the other is a model oil. It all depends on the density of the oil, pressure, temperature and compositions of the oil

Squalane is soluble in CO<sub>2</sub> in the presence of surfactant at experimental conditions and values mentioned in this work are the ones at which Squalane drop was most stable.

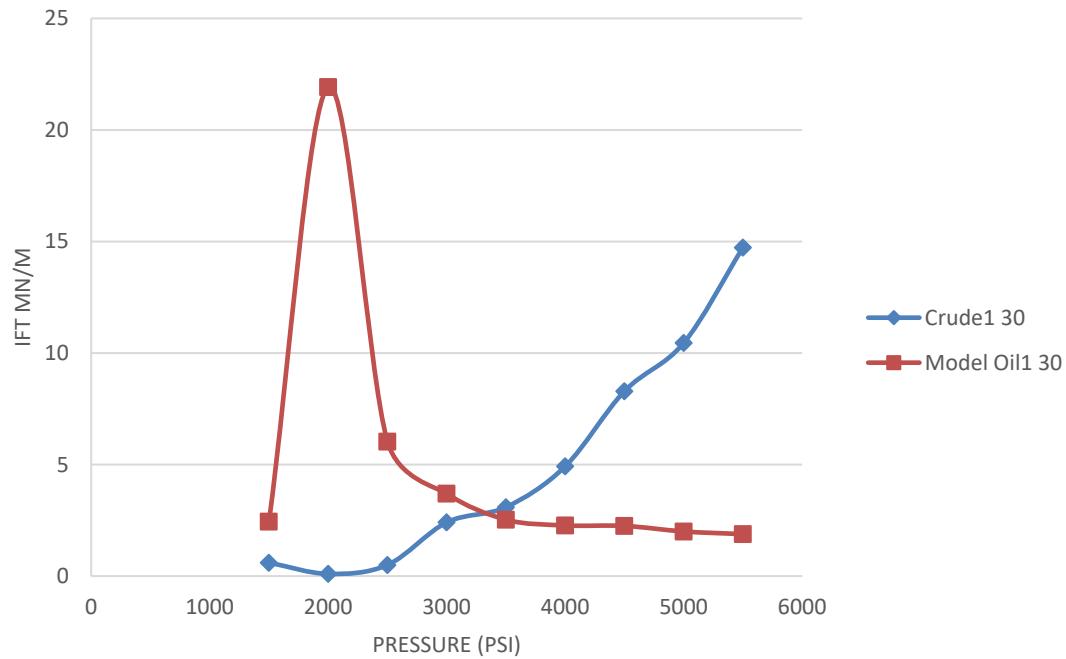

Figure 51: Interfacial tensions of Oils at 30°C

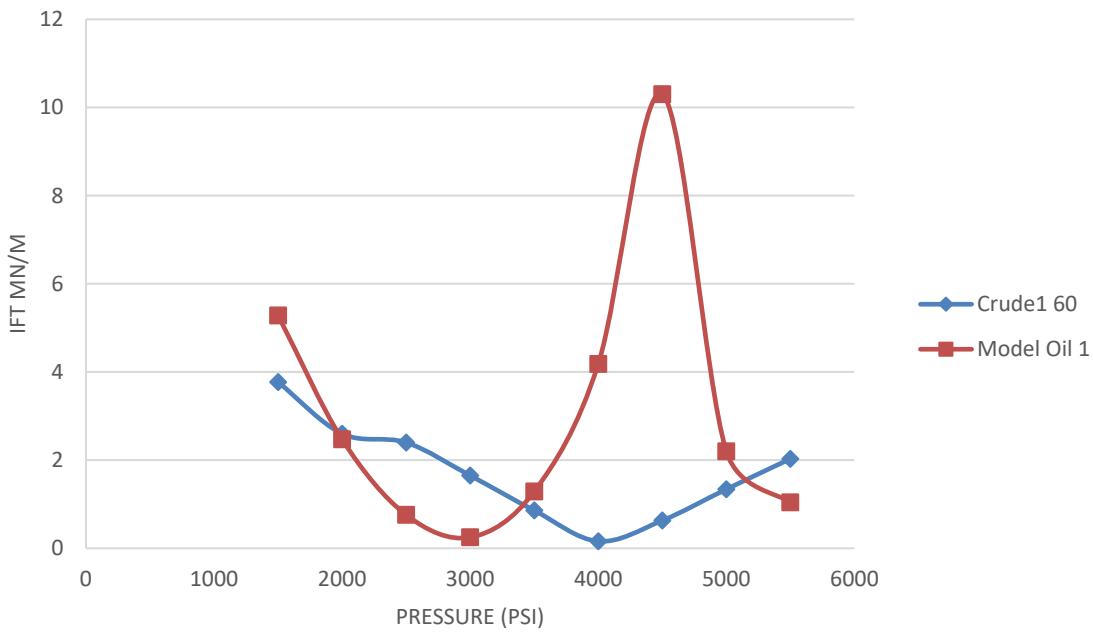

Figure 52: Interfacial Tensions of Oils at 60°C

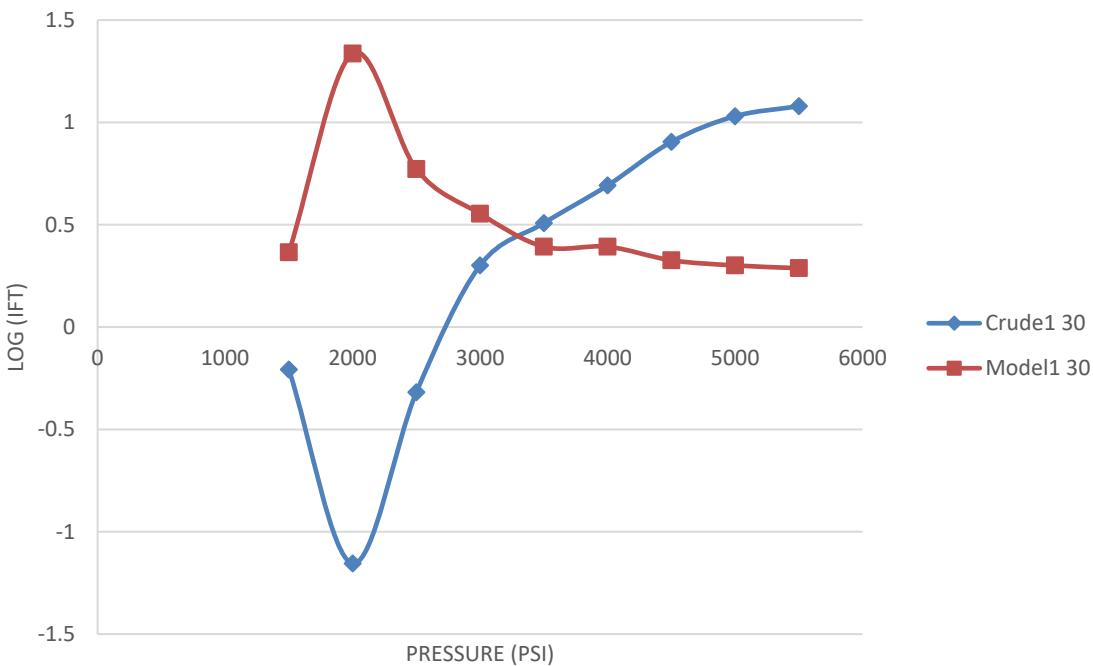

Figure 53: Log (IFT) vs Pressure for Oils at 30°C

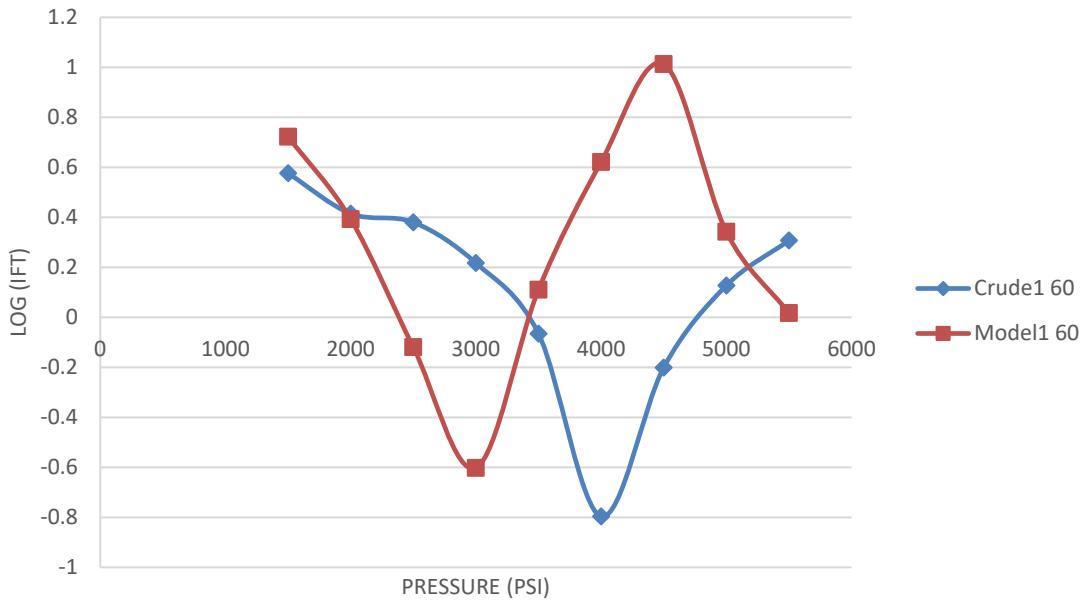

Figure 54: Log (IFT) vs Pressure for Oils at 60°C

Solubility of Squalane in CO<sub>2</sub> increases with increase in pressure therefore at high pressures, drop remains stable for very short period. Different readings were taken for the same point to get an average.

#### **4.2.4 Experiments which were unsuccessful**

Other oils that were used for IFT experiments but the results could not be generated have been mentioned below:

##### **4.2.4.1 Toluene**

This single model was very light and did not form a drop in CO<sub>2</sub> at either 30 or 60°C. It would become a gas and mix with CO<sub>2</sub>.

#### **4.2.4.2      Pentadecane**

Pentadecane would produce a drop only at low pressures however higher values could not be taken. Since this same oil had to be used for contact angle and IFT experiment was not successful, therefore it wasn't used for contact angle experiments as well.

#### **4.2.4.3      Crude Oil 2**

This an API 40 crude oil of a Saudi Arabian field. During IFT experiments, the lighter components of the oil are highly soluble in CO<sub>2</sub> making it difficult to measure correct values of IFT (Figure 121). Since for Young-Laplace equation to be solved for IFT, the drop has to be perfectly in balance with the gravity, hanging itself. Therefore, IFT values could not be generated. However, contact angle values were measured with this oil.

Also there were other types of experiments that could not be performed were:

#### **4.2.4.4      Use of (50% BSS3 and 50% CO<sub>2</sub>) as Bulk Fluid**

For this experiment, instead of few drops of BSS3, 10cc of cell was filled with BSS3 (since the whole cell has a capacity of 20cc). The remaining would be filled by CO<sub>2</sub>. CO<sub>2</sub> does not have very high solubility for Brine even at very high temperatures and pressures. Therefore, the cell would remain half filled with liquid at all pressures, also a layer of foam would accumulate on the interface between CO<sub>2</sub> and BSS3. Therefore, if a drop was generated, it would be generated in the CO<sub>2</sub> portion of the cell but when the drop grown larger, it would touch the interface and therefore mix with it which would make it impossible for the DSA software and camera to distinguish between oil drop and the foam on the interface. Also BSS3 is heavier than Oil, therefore it would not allow the drop to enter the liquid region and therefore it distorted the drop shape of the oil.

#### **4.2.4.5      Use of (CO<sub>2</sub>+ Oil) as bulk fluids and BSS3 as drop fluids**

Oil could not be used in the bulk phase as it would make whole of the cell and its glass “black” making it impossible to see through the camera. No experiment in the literature has been performed with crude oil as a bulk fluid for the same reason.

## **CHAPTER 5**

### **RESULTS AND DISCUSSION OF CONTACT ANGLE**

### **EXPERIMENTS**

Contact Angle is the measure of Wettability of a fluid with a rock surface. Higher the contact angle means lesser is the wettability and vice versa.

Wettability is an important parameter for Enhanced Oil recovery processes since the sole purpose of EOR is to decrease the residual oil saturation inside the reservoir. In case of Surfactant-Alternating-Gas (SAG) process, use of surfactant can not only decrease the interfacial tension of the fluids, but also decrease the wettability of the fluids. Experiments were performed where CO<sub>2</sub>, Brine, Surfactant and Oil would coexist on a dolomite rock in order to study the wettability and the effect of pressure at a particular temperature (60°C in our case).

The purpose of performing these experiments was to change the wettability of dolomite rock from oil wet to gas-wet. [88] first used the word gas-wetting in their work where they used two chemicals to alter the wettability of rock from liquid wetting to gas-wetting. Fluorosurfactant has the ability to adsorb on the mineral surface for long-term wettability alteration.[89]

Before the start of actual experiments, three experiments with Squalane were performed on different rock surfaces to test the effect of surface polishing.

## **5.1 Test Experiments**

Three experiments were performed to study the effect of polishing and saturating the rock surface.

### **5.1.1 Polishing with silicon epoxy, not saturated with oil**

This experiment was performed where the rock disk was polished with silicon epoxy. Use of silicon epoxy completely sealed the porosity of the rock. Use of silicon epoxy has a disadvantage that it changes the composition of the rock by entering inside the pores and therefore the value for contact angle measurement will not be actual representative of dolomite.

### **5.1.2 Unpolished, unsaturated rock disk**

Rock disk was not polished neither was it saturated with oil prior to performing the experiments in order to study the effect of adsorption of oil on contact angle.

### **5.1.3 Polished by grinding the surface, saturated with oil**

Rock disk was polished by grinding machine using a specially fabricated holder. Later the prepared disk was kept dipped in a closed container containing oil (squalane). This container was kept in the oven at experimental conditions (60°C) for 24 hours.

The results of above three experiments has been shown in **Error! Reference source not found..** Because of least absorption, epoxy-polished gave higher contact angle values. The unsaturated and unpolished rock gave lowest because of high effects of absorption. The non-epoxy, polished and saturated rock disk's results were considered logical to be used for all experiments since saturated rock is representative of real rock situation and

polishing rock by merely grinding (not epoxy) makes the rock horizontal and smooth allowing for accurate measurement of contact angle.

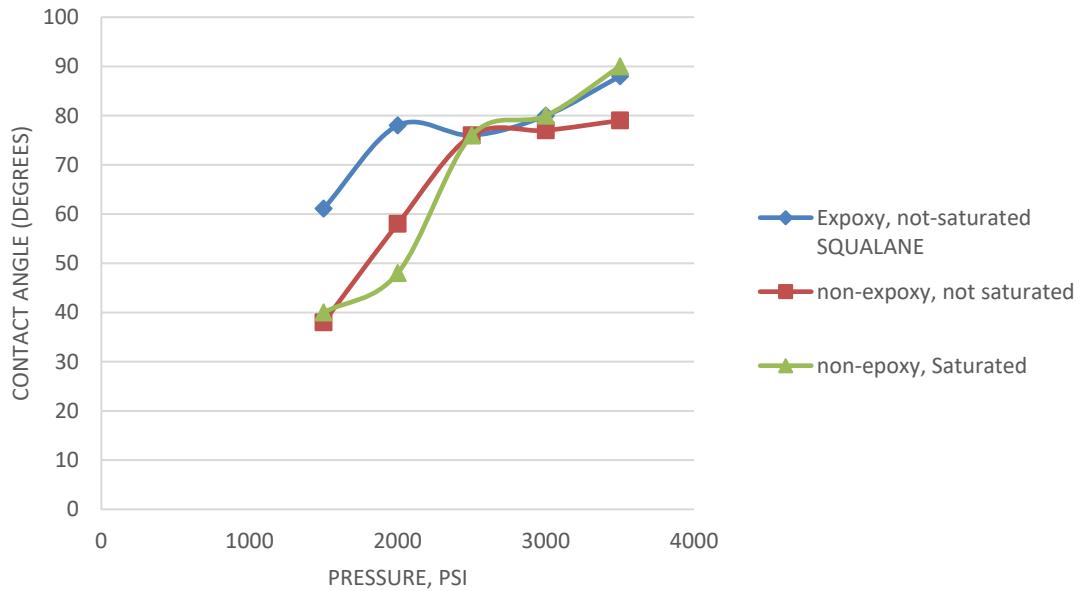

Figure 55: Results of Test CA Experiments with Squalane

According to the experimental plan in chapter 3, contact angle experiments of three different oils were performed with oils as drop fluids and CO<sub>2</sub> saturated with BSS3 as bulk fluid. The core disk used was Guelph Dolomite for all experiments.

## 5.2 Oil drop on Guelph Dolomite in the presence of CO<sub>2</sub> and BSS3

The decrease in oil wettability from Figure 56 to Figure 60 can be explained by the water and oil repellency of Fluorosurfactants because of its small Van der Waal's forces between fluorine and carbon atoms.

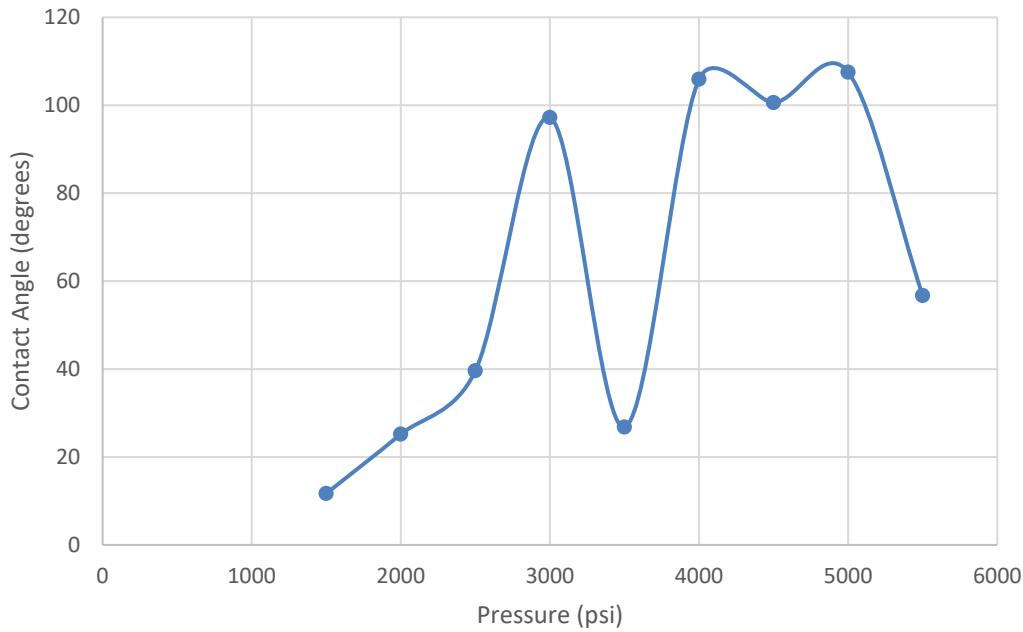

Figure 56: Contact Angle of Crude oil 1 at 60°C and different pressures

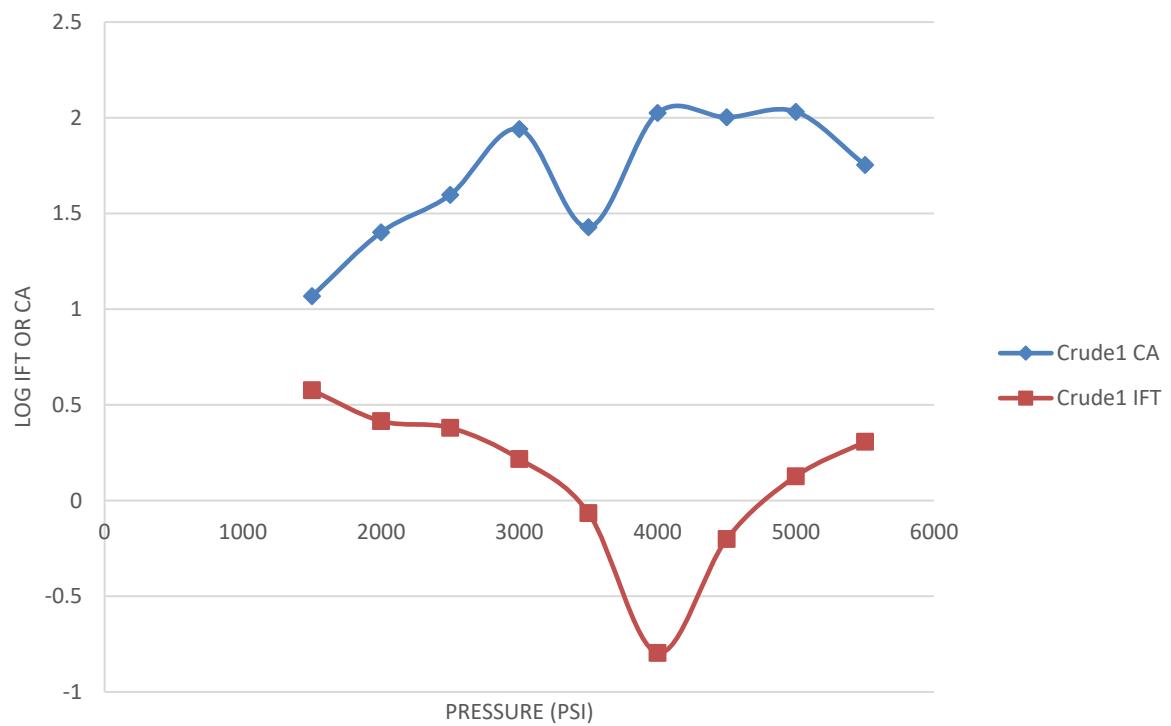

Figure 57: Semi-Log plot of both IFT and CA for Crude oil 1

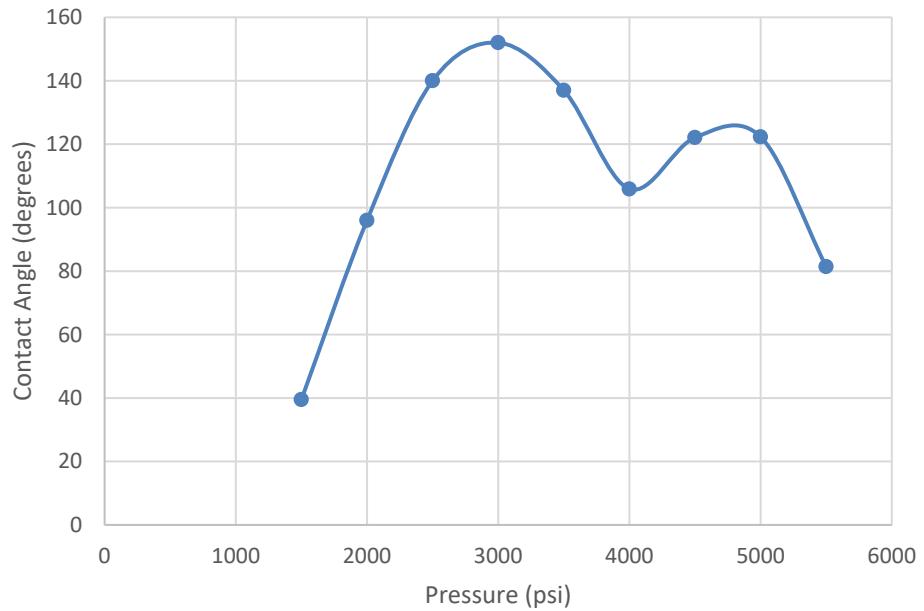

Figure 58: Contact Angle of Squalane Drop at 60°C at different pressures

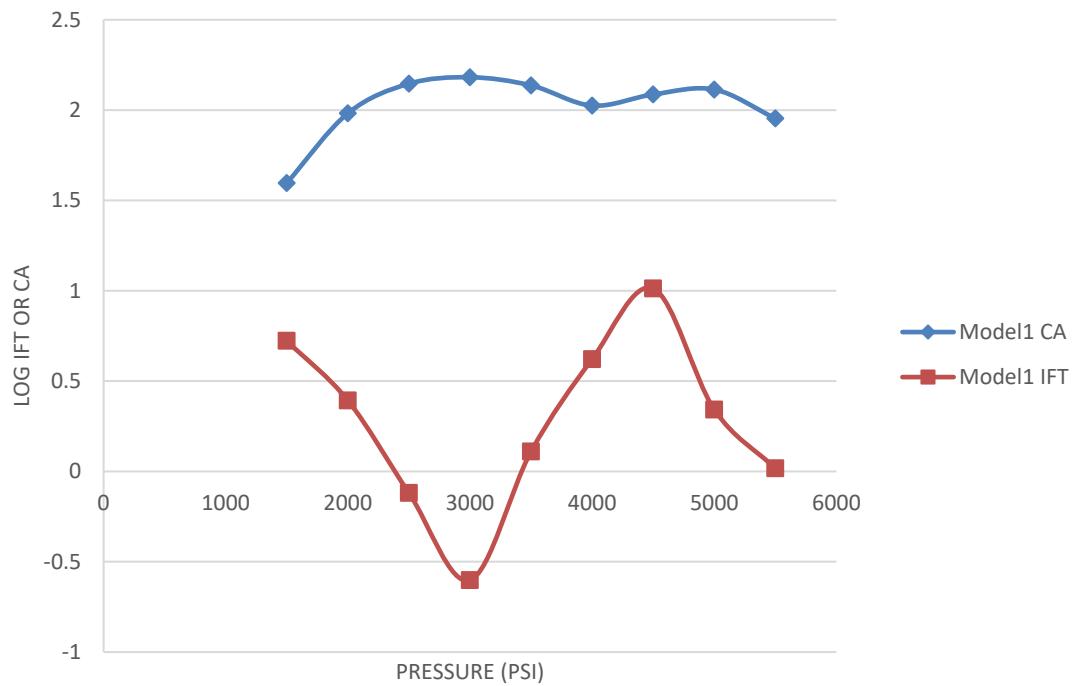

Figure 59: Semi-log Plot of both IFT and CA for Model Oil 1

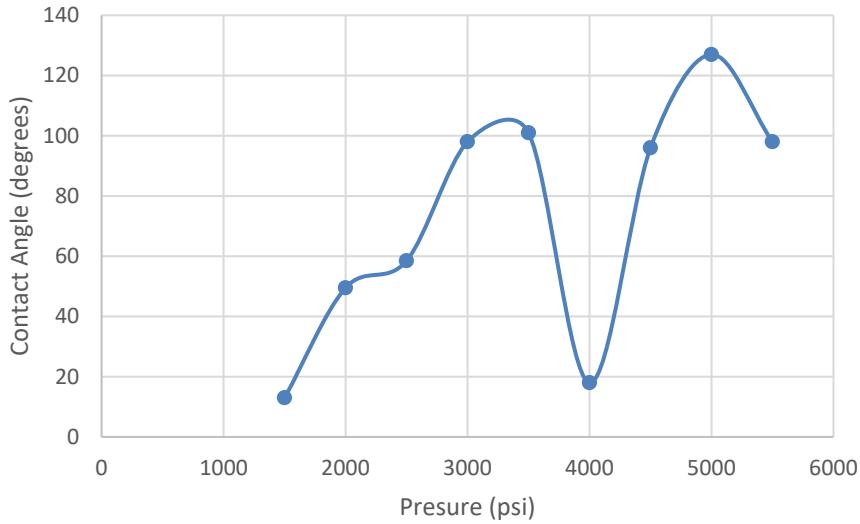

Figure 60: Contact Angle of Crude oil 2 at 60°C and different pressures

### 5.3 Comparison of All three oils (Crude oil 1, Arabian Light, Squalane)

Figure 61 and Figure 62 show the comparison of all the previously mentioned contact angle experiments on a single graph.

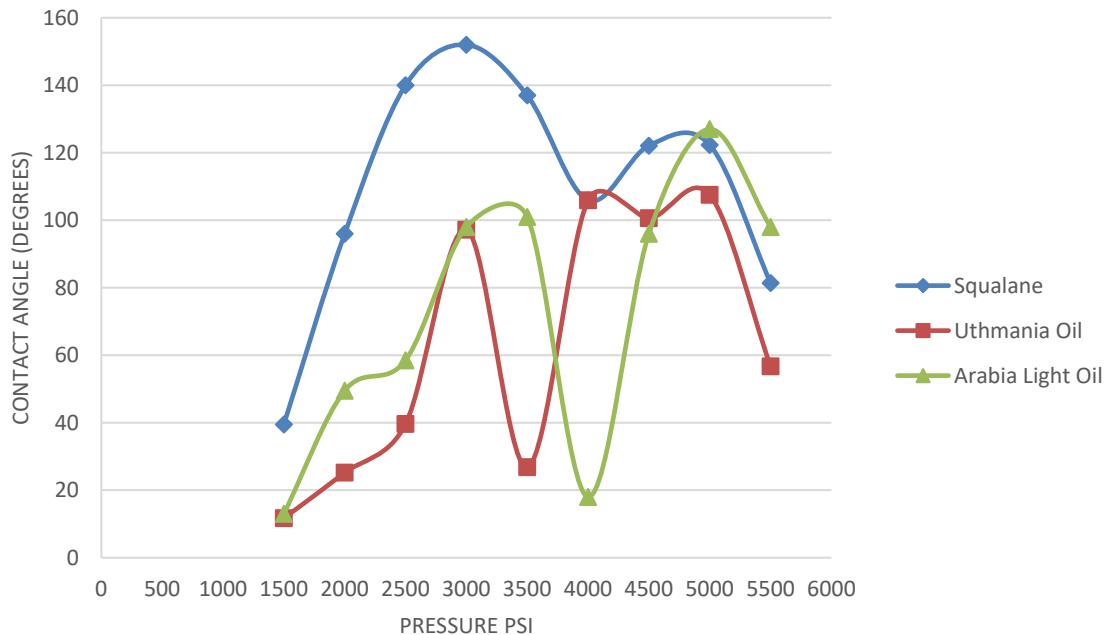

Figure 61: Contact Angles of Oils at 60°C at different pressures

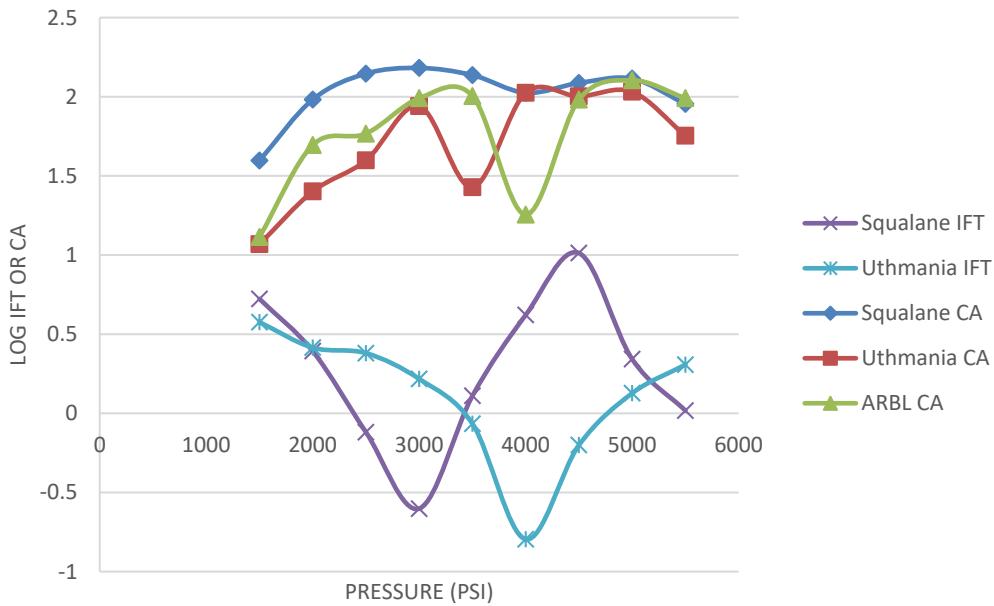

Figure 62: All Log plots of oils

Fluorine atoms had a very strong electronegativity of 4.0. On the contrary, fluorocarbon molecules were extremely resistant to oxidation because fluorine atoms, with an electronegativity of 4.0, were attached to their carbon atoms, thereby bringing the carbon atoms into a more oxidized state than that of those bound to the oxygen atoms of an electronegativity of 3.6. Halogens were generally strongly electronegative with high bond energy between carbon and fluorine (in particular) which had the strongest bond energy at 484 kJ/mol. Moreover, fluorine atoms were small in size (next to the smallest hydrogen atoms) and their van der Waals and covalent bond radii were larger than those of the hydrogen atoms by only 10%, or so. This rather small difference in size caused the hydrocarbon chains to have a zigzag structure and the fluorocarbon chains to have a rigid rod-like shape with a period of twist with 13 carbon atoms. In addition, the carbon

skeleton (within this rigid structure) was covered by densely packed fluorine atoms that were attached to the carbon atoms, much like a rod with a fluorine sheath on it. The protective action of the fluorine atoms is shown in Figure 63.

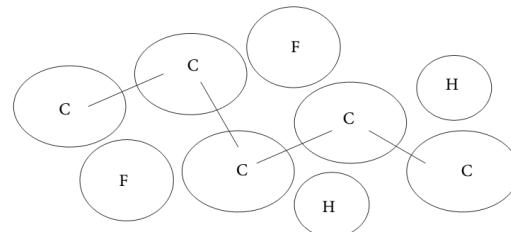

FIGURE 5: Protective action of fluorine atoms.

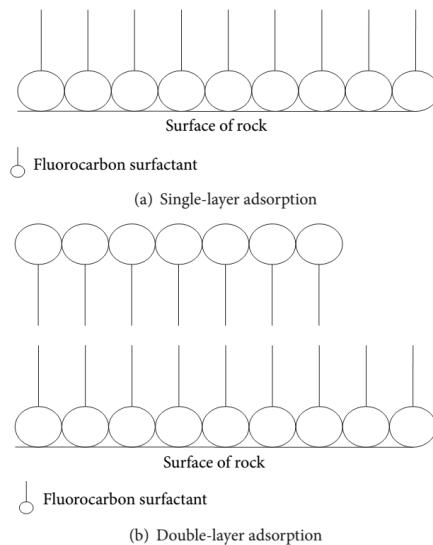

Figure 63: Adsorption of Fluorosurfactant on rock surface [90]

The nature of fluorine atom leads to the water and oil repellency characteristic of the Fluorosurfactants. Fluorine atom has the strongest electronegativity and the smallest atomic polarizability among the elements. Its atom radius is also smaller than other elements except for hydrogen. This enables the formation of a strong carbon-fluorine bond thereby forming the perfluoroalkyl group having weak intermolecular Van der Waals force and small interaction with other substances such as water and hydrocarbons.

Then, the surfaces of the disks get altered to gas-wetting because of the water and oil repellency characteristic of the fluorosurfactant.

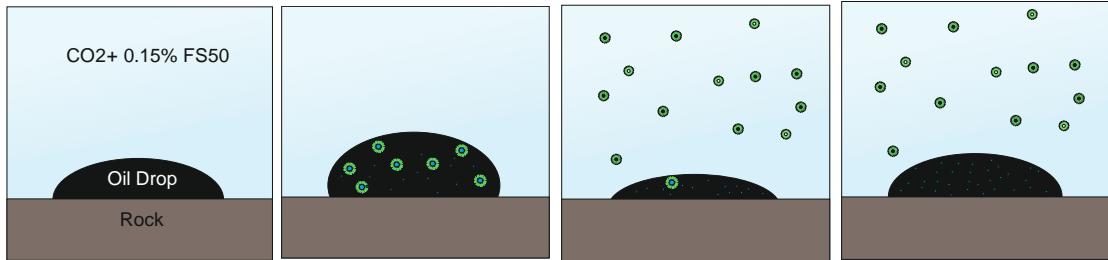

Figure 64: Formation of micro-emulsions explained graphically

However, between 3000 psi to 4000 psi, the CA would show a decrease i.e. the rock becomes oil wet. But a further increase in pressure causes the wettability to come back to its original trend of decreasing value i.e. increasing contact angle. This trend of sudden decrease is continuous in all kinds of oils; therefore, it is due either due to any property of CO<sub>2</sub> or the fluorosurfactant used. The explanation for similar behavior has been given by Wang et al. in 2013 that the cause of reduction in gas-wetting is due to double-layer adsorption of the fluorosurfactant (Figure 63) but this is valid if high surfactant/unoptimistic concentrations are used [90]. Since in our case the pressure of the system is causing a change, our surfactant is forming micro-emulsions inside the system and it is always close to the PIP (phase inversion pressure) which can be observed from Figure 62 therefore the whole process can be explained graphically using Figure 64. For every pressure, a new drop was formed on a fresh surface and then allowed to stabilize for some time. Increase in pressure causes an increase in CA i.e. decrease in oil wettability. This is due to CO<sub>2</sub>-in-oil micro-emulsions and also due to CO<sub>2</sub> being dissolved in the oil. However, as the system reaches the transition zone, the micro-

emulsions become unstable and start breaking until a certain point where oil-in-CO<sub>2</sub> and Brine-in-CO<sub>2</sub> micro-emulsions form. Contact angle then continues to increases with increase in pressure due to dissolved CO<sub>2</sub>.

#### **5.4 Correlation Based on Experimental Data Using Artificial Neural Network (ANN)**

The above trends can be made into a correlation that depend on pressure, density and IFT.

$$CA_n = \left[ \sum_{i=1}^N w_{2i} \left( \frac{2}{1 + e^{-2(w_{1i,1} P_n + w_{1i,2} IFT_n + w_{1i,3} |\rho_{CO_2} - \rho_{oil}|_n + b_{1i})}} \right) \right] + b_2$$

Where the w<sub>1</sub>, w<sub>2</sub>, b<sub>1</sub> and b<sub>2</sub> are the weight matrix of input layer, weight vector of hidden layer, bias vector of input layer and bias of hidden layer respectively.

i = Number of hidden layer neurons

N = Total number of neurons in hidden layer

b<sub>1</sub> = Bias vector for input layer

b<sub>2</sub> = Bias of hidden layer

n = Subscript ‘n’ shows normalized parameter

w<sub>1</sub> = Weight matrix of input layer

w<sub>2</sub> = Weight matrix of hidden layer

IFT = Interfacial tension (mN/m)

CA<sub>n</sub> = Normalized output of the output layer

P = Pressure

$$\rho_{CO_2} - \rho_{Oil} = \text{Density diff of CO}_2 \text{ and oil}$$

This correlation was made using two of the five oils used (Crude Oil 1 and Model Oil) for CA and IFT measurements because IFT values of crude oil 2, model oil 2 and model oil 3 could not be obtained.

70% of data was used for training the ANN model and finding weights. It was then tested using 30% of the data. Figure 65 shows a plot between ANN Model data and Experimental results. Except for two points, the model shows good agreement with experimental data. Figure 66 is a similar plot for testing data of ANN model with experimental results which shows good agreement.

Both experimental values and values predicted from the model have been plotted in Figure 67 and Figure 68. The model can predict the rise and fall of contact angle but not all points could be accurately predicted. A lot more experimental data for oils is required at more ranges of pressure and temperature in order to decrease the error.

This correlation can be used for densities, pressures and IFTs lying in the range used in this work and at 60°C.

Correlation buildup parameters have been mentioned in Appendix F. This correlation requires IFT, Density difference of the Bulk and drop fluids, and Pressure as input parameters to find Contact Angle on a surface of Dolomite. The results of correlation match with experimental data with 8.4% average error.

## **5.5 Discussions**

The ultimate objective of this thesis research was to understand the interfacial phenomenon of fluids which co-exist during (Surfactant-Alternating-Gas) processes. If the interfacial tension and contact angle could be reduced, high oil recovery by an EOR process can be achieved. The data set obtained from this experiment can also help understand the use of different surfactants during SAG processes.

Usually in Middle East, sea water can be easily utilized for injection during EOR process. This work explains how good it can be if sea water could be diluted to reduce the salinity to enhance the oil recovery. Also, Crude oil 1 and Crude oil 2 are two crude oils used in this work from Saudi Arabian oil field, both having different APIs to see the effect of Oil densities at interfacial level. Squalane is a model oil that has been used as a test case but however the trends lie matching the trends of crude oil therefore giving a good idea how multi or single component oils can behave in similar conditions.

Brine1 used was a recipe of sea water prepared in laboratory. It is a multi-component brine that behaved almost similar to other single component brines in the literature, however the values may be different. Effect of Brine salinity was observed by diluting this same brine with deionized water and then running experiments on them again. Effect of Pressures was measured every time on a new drop. Alfoterra and FS-50 behave almost similarly but FS-50 gives a much lower interfacial tension that is why FS-50 was considered for further experimental sets.

Interfacial tension experiments were performed on the following systems:

1. CO<sub>2</sub> and 4 types of Brines

2. CO<sub>2</sub> and Brine4 (lowest salinity) with 3 types of Surfactants
3. CO<sub>2</sub> (saturated with Brine4 Containing FS50) with 5 types of Oils but three were unsuccessful.

At 9 different pressures from 1500 to 5500 psi and 3 temperatures 30°C, 60°C and 90°C.

Contact Angel experiments were performed on the following system:

1. CO<sub>2</sub> with 5 types of Oils in the presence of Brine Surfactant Solution (FS-50) (two were unsuccessful).

At 9 different pressures from 1500 to 5500 psi and at 60°C.

## **CHAPTER 6**

### **CONCLUSIONS & RECOMMENDATIONS**

#### **6.1 Conclusions**

The results from IFT experiments that were described in chapter 4 lead us to the following conclusions:

- 1- Density of Fluids increase with increase in temperature
- 2- At high salinity, IFT is independent of temperature.
- 3- Lesser the salinity, lesser will be the interfacial tension of the fluids
- 4- For brines and brine-surfactant solutions IFT decreases with increase in pressure
- 5- Higher the temperature, higher will be the IFT of Brines
- 6- Density difference can be used to generalize the behavior of IFT to some extent, for CO<sub>2</sub>/Brine and CO<sub>2</sub>/Brine/Surfactant Systems
- 7- IFT decreases with time, so best time to measure IFT is when both fluids come to an equilibrium
- 8- Drop Volume (solubility) increases with pressure and decreases with temperature
- 9- Alfoterra (alkyl ether sulfate surfactant) is not stable at temperatures higher than 60°C
- 10- Armovis (viscoelastic) gives quite low IFT values but fluorosurfactant give ultra-low IFTs
- 11- The lowest IFT out of “Armovis EHS, Alfoterra and FS-50” was shown by FS-50
- 12- For Oil-surfactant Systems, pressure behavior cannot be generalized.

13- Increase in temperature causes a delay of emulsification for Oil, BSS and CO<sub>2</sub> Systems

14- The best surfactant to be used with CO<sub>2</sub> is a fluorosurfactant based on the results that it provided ultra-low IFT and high contact angles.

15- At high temperature, emulsification is thermodynamically stable and the glass of the cell becomes completely blurred making it difficult to see.

16- Fluorosurfactant caused formation of micro-emulsions inside the cell.

17- Surfactant preference change with both temperature and pressure.

18- Minor error close to the critical point of CO<sub>2</sub> can give large errors.

19- IFT Experiments performed with Toluene, Pentadecane and Crude oil 2 were unsuccessful because they were very light and could not generate drop properly in CO<sub>2</sub>.

20- It was tried to use 50% CO<sub>2</sub> and 50% BSS3 in the cell as Bulk fluid however the experiment was unsuccessful because CO<sub>2</sub> does not have high solubility and the oil drop could not be distinguished in presence of a layer of foam on the interface of CO<sub>2</sub> and BSS3.

21- Oil cannot be used as a Bulk fluid because it makes the whole cell black making it impossible to see the drop from the camera.

The results from contact angle experiments that were described in chapter 4 lead us to the following conclusions:

1- Fluorosurfactant plays a critical role in decreasing wettability of oil in the presence of CO<sub>2</sub> and brine.

- 2- At any point close to PIP (Phase inversion pressure) the rock becomes oil wet because of the alignment of surfactant atoms due to which surfactant changes preference.
- 3- Increase in pressure causes increase in gas-wettability of dolomite rock only until certain high pressure.
- 4- There is a transition zone for CA measurements where the rock becomes oil-wet from gas wet. This transition zone for each oil depends on temperature and pressure conditions and is close to phase inversion pressure (PIP).
- 5- This trend of static contact angle has been used to develop simple correlation based on the data given from these experiments. This correlation depends on IFT, pressure and density difference of fluids at 60°C within the range of this experimental data. It can be used with CO<sub>2</sub>, florosurfactant, Oil and dolomite systems.
- 6- The given correlation has an average error of 8.4% for matching the experimental data ANN model.

## 6.2 Recommendations

1. Further study of IFT with oils of different asphaltenes percentage and aromatics in the presence of CO<sub>2</sub> and FS-50 is needed.
2. More pressure and temperatures ranges need to be studied for the Oil/Brine/Surfactant/CO<sub>2</sub>/Dolomite system for both IFT and CA analysis.
3. Effect of change in surfactant concentration on micro-emulsions needs to be studied.
4. Playing with head and tail of surfactant can reveal valuable information.
5. Effect of change in pH on all experiments in this work needs to be studied.
- 7- Molecular simulation of contact angle experiments is required to study how the thin-film layer near the surface of the rock would look like at various conditions.

- 8- Fluorosurfactant needs to be used together with hydrocarbon surfactants and/or chelating agents to study behavior with crude oils in the presence of brine and CO<sub>2</sub>.
- 9- The stability of micro emulsions needs to be quantified.

## APPENDICES

## APPENDIX E: DROP PROFILES

### Brines

**At 30°C**

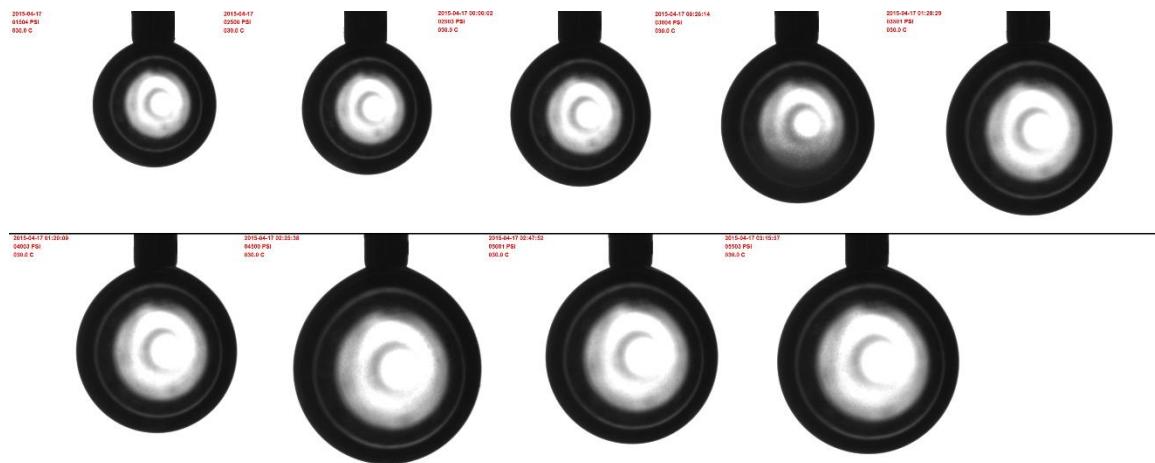

Figure 96: Drop profile- Brine1 at pressures (left to right) 1500 to 5500 psi and 30°C

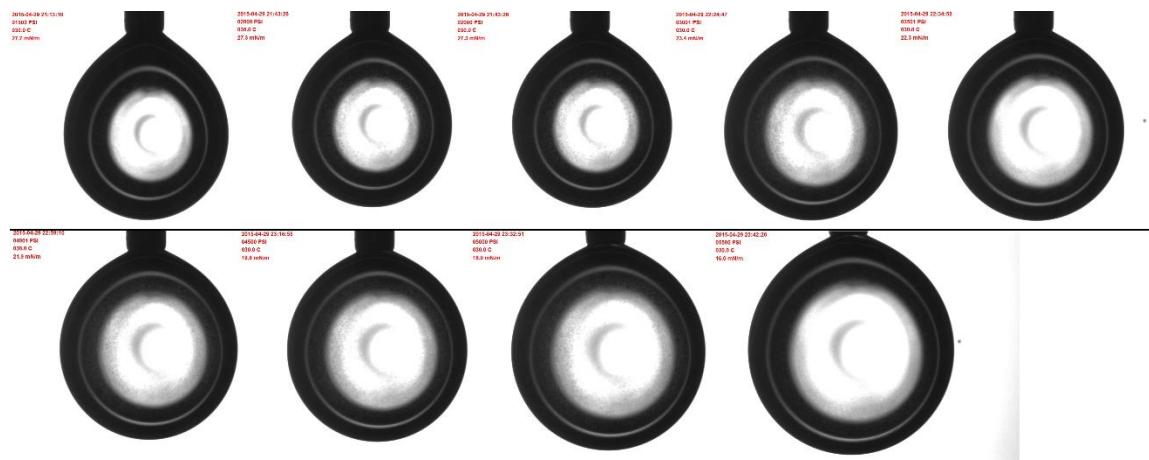

Figure 97: Drop profile- Brine2 at pressures (left to right) 1500 to 5500 psi and 30°C

Figure 98: Drop profile- Brine3 at pressures (left to right) 1500 to 5500 psi and 30°C

Figure 99: Drop profile- Brine4 at pressures (left to right) 1500 to 5500 psi and 30°C

### At 60°C

Figure 100: Drop profile- Brine1 at pressures (left to right) 1500 to 5500 psi and 60°C

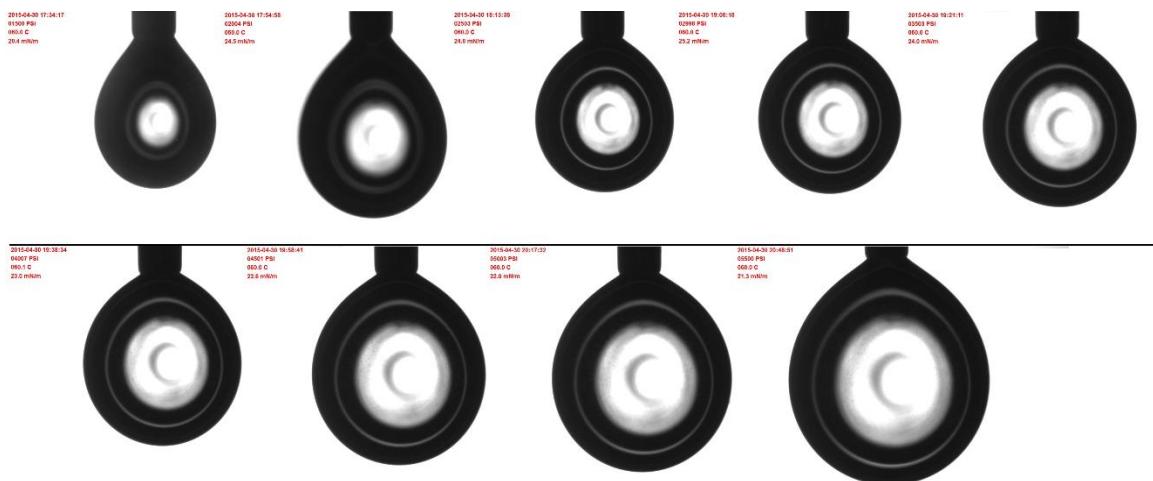

Figure 101: Drop profile- Brine2 at pressures (left to right) 1500 to 5500 psi and 60°C

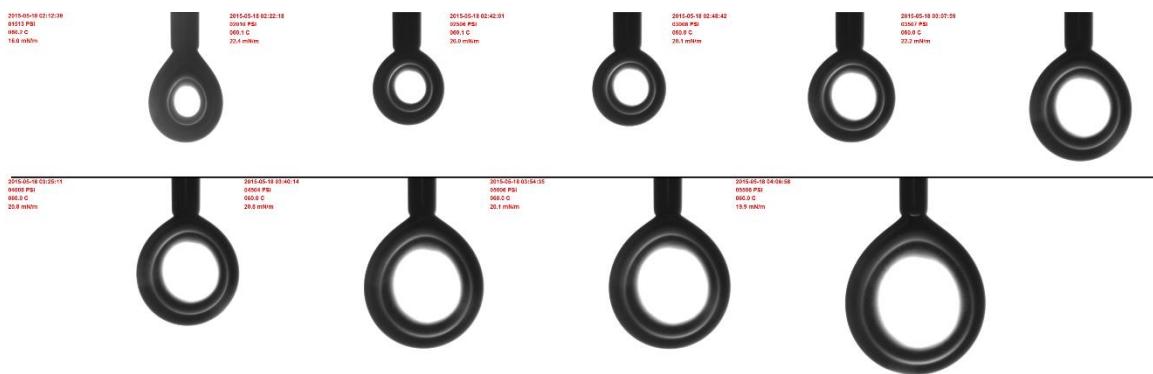

Figure 102: Drop profile- Brine3 at pressures (left to right) 1500 to 5500 psi and 60°C

Figure 103: Drop profile- Brine4 at pressures (left to right) 1500 to 5500 psi and 60°C

#### At 90°C

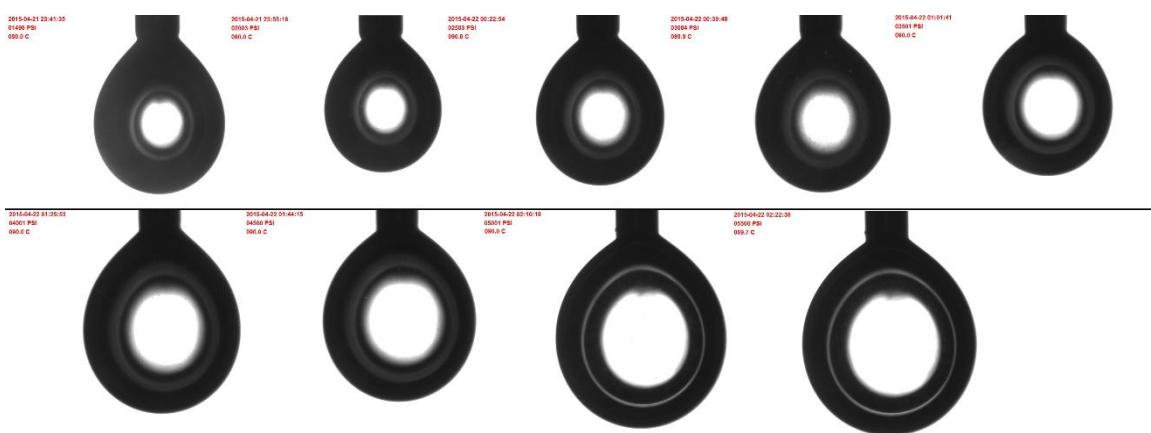

Figure 104: Drop profile- Brine1 at pressures (left to right) 1500 to 5500 psi and 90°C

Figure 105: Drop profile- Brine2 at pressures (left to right) 1500 to 5500 psi and 90°C

Figure 106: Drop profile- Brine3 at pressures (left to right) 1500 to 5500 psi and 90°C

Figure 107: Drop profile- Brine4 at pressures (left to right) 1500 to 5500 psi and 90°C

## Brine-Surfactant Solutions

At 30°C

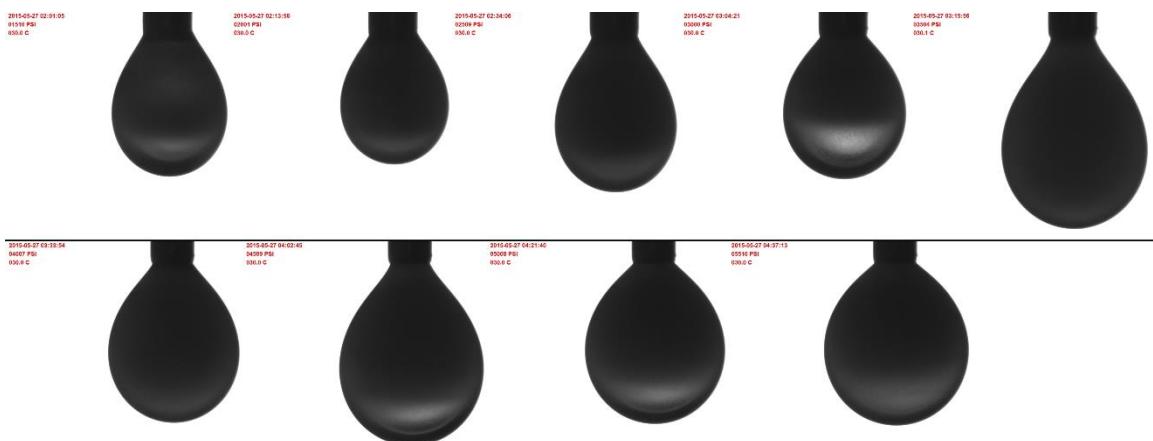

Figure 108: Drop profile- BSS1 at pressures (left to right) 1500 to 5500 psi and 30°C

Figure 109: Drop profile- BSS2 at pressures (left to right) 1500 to 5500 psi and 30°C

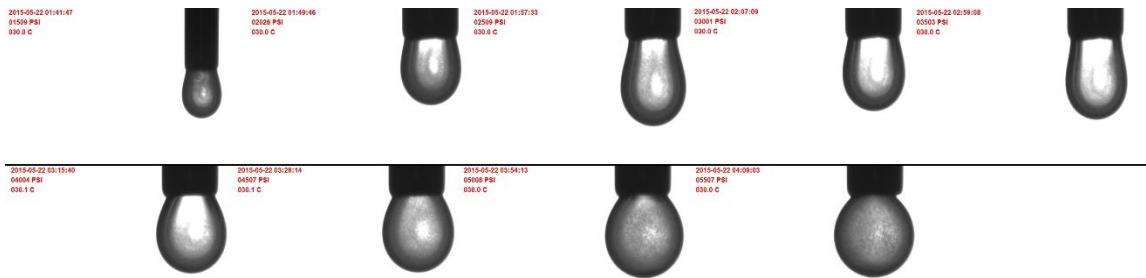

Figure 110: Drop profile- BSS3 at pressures (left to right) 1500 to 5500 psi and 30°C

### At 60°C

Figure 111: Drop profile- BSS1 at pressures (left to right) 1500 to 5500 psi and 60°C

Figure 112: Drop profile- BSS2 at pressures (left to right) 1500 to 5500 psi and 60°C

Figure 113: Drop profile- BSS3 at pressures (left to right) 1500 to 5500 psi and 60°C

#### At 90°C

Figure 114: Drop profile- BSS1 at pressures (left to right) 1500 to 5500 psi and 90°C

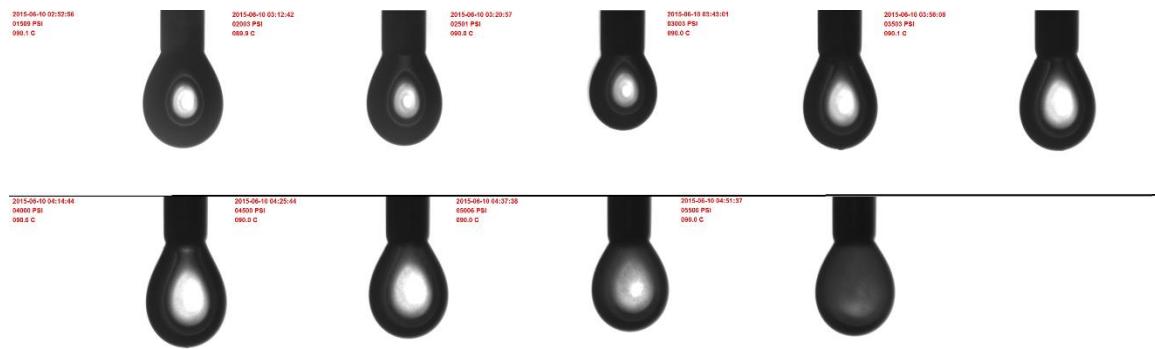

Figure 115: Drop profile- BSS2 at pressures (left to right) 1500 to 5500 psi and 90°C

Figure 116: Drop profile- BSS1 at pressures (left to right) 1500 to 5500 psi and 90°C

## Oils

At 30°C

Figure 117: Drop profile- Squalane at pressures 1500 to 5500 psi and 30°C

Figure 118: Drop profile- Crude1 at pressures 1500 to 5500 psi and 30°C

**At 60°C**

Figure 119: Drop profile- Squalane at pressures 1500 to 5500 psi and 60°C

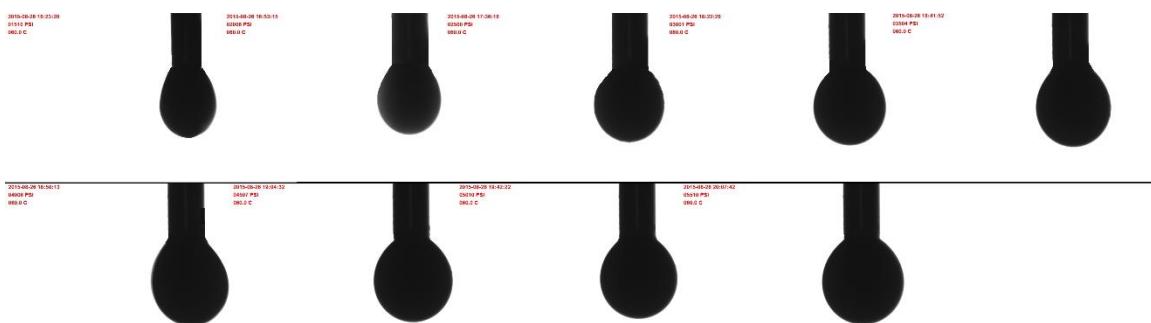

Figure 120: Drop profile- Crude1 at pressures 1500 to 5500 psi and 60°C

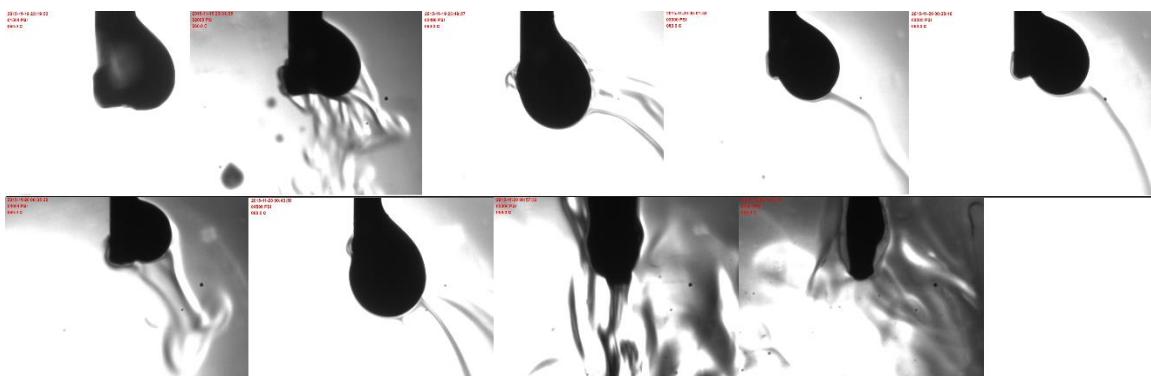

Figure 121: Drop profile- Crude2 at pressures 1500 to 5500 psi and 60°C

## Contact Angle Experiments

### Crude oil 1 at 60°C

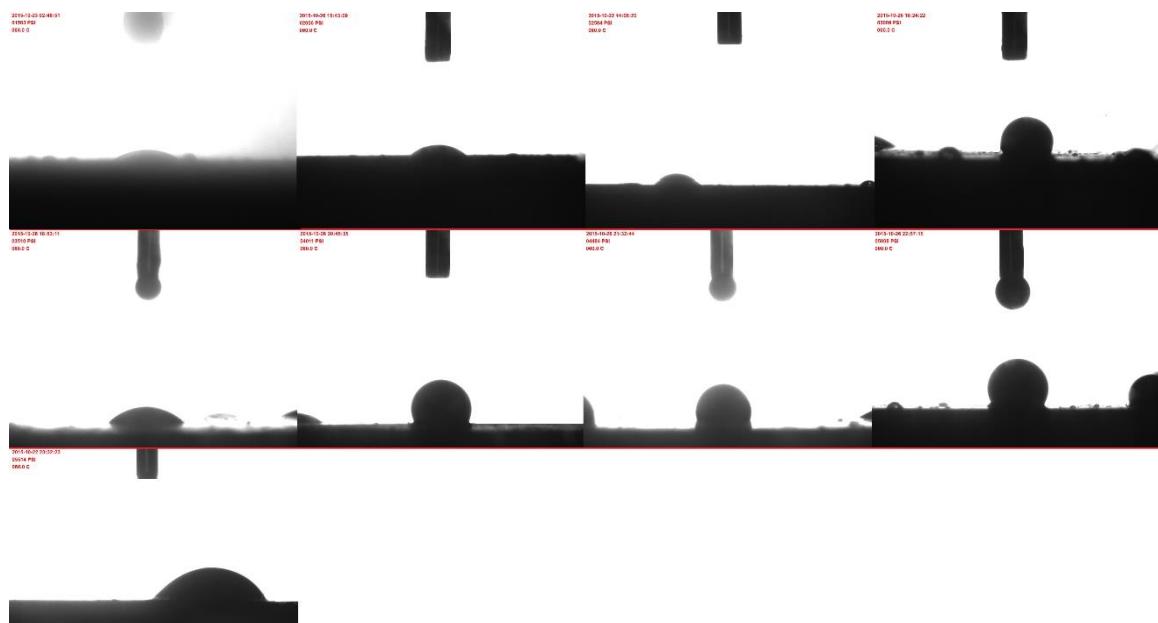

Figure 122: CA Drop profile- Crude1 at pressures 1500 to 5500 psi and 60°C

### Squalane at 60°C

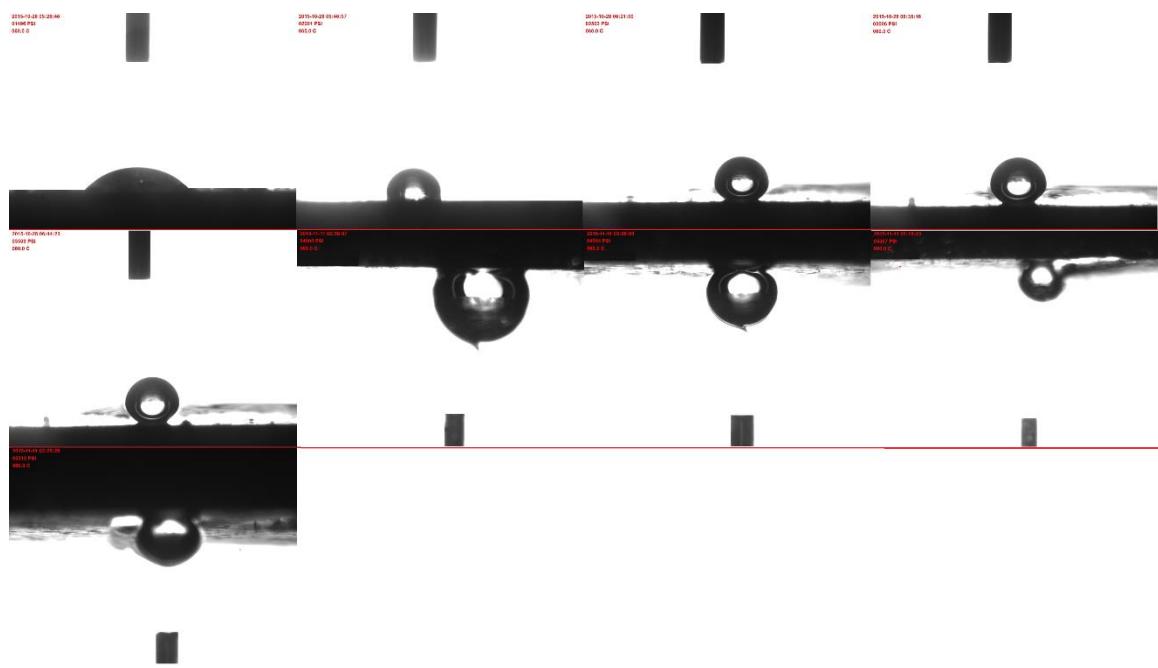

Figure 123: CA Drop profile- Squalane at pressures 1500 to 5500 psi and 60°C

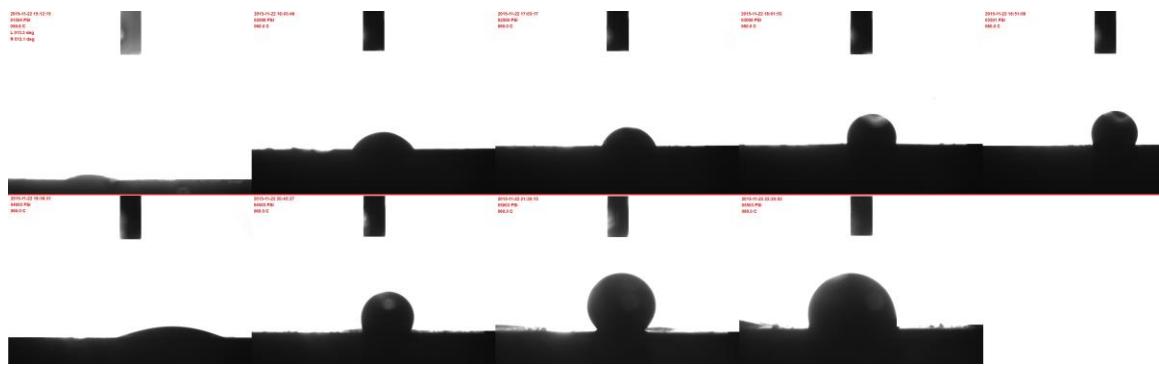

Figure 124: CA Drop profile- Crude2 at pressures 1500 to 5500 psi and 60°C

## APPENDIX F

### Correlation Parameters

Table 36: Parameters of CA Correlation

<b>w<sub>1,i,1</sub></b>	<b>w<sub>1,i,2</sub></b>	<b>w<sub>1,i,3</sub></b>	<b>w<sub>2,i</sub></b>	<b>b<sub>1,i</sub></b>	<b>b<sub>2</sub></b>
2.461168	0.961075	-2.05418	-1.1217	-2.57961	-0.63986
0.415262	2.552612	-1.53557	0.649854	-2.34526	
1.806469	-1.91561	2.040436	-1.41558	-1.51262	
1.306621	-2.44383	1.631914	2.313308	-0.91655	
2.14467	-2.34128	1.3602	1.207241	-0.279	
-5.13255	1.220157	-0.90888	2.776423	0.304125	
-3.70864	1.545599	-3.12364	3.088561	-1.51209	
7.414321	3.083599	2.944771	4.518283	4.724991	
-3.03451	0.606316	0.549544	0.517334	-2.16638	
1.809452	-2.40584	-1.08831	0.939483	2.823868	

#### **Normalization:**

Input parameters should be normalized for the new correlation and then the output must be de-normalized between -1 and +1 using traditional two-point formula given below:

$$\frac{Y - Y_{min}}{Y_{max} - Y_{min}} = \frac{X - X_{min}}{X_{max} - X_{min}}$$

$$Y = \frac{X - X_{min}}{X_{max} - X_{min}} (Y_{max} - Y_{min}) + Y_{min}$$

Where

Y = Input Parameter in normalized form

$$Y_{\max} = 1$$

$$Y_{\min} = -1$$

$X_{\min}$  = Input Data maximum value.

$X_{\max}$  = Input Data minimum Value

$X$  = Input Parameter normalized form

$$Y = \frac{X - X_{\min}}{X_{\max} - X_{\min}} * 2 - 1$$

Therefore, the output obtained by using the correlation will be in normalized form that must be de-normalized using the following equation

$$CA = \frac{(152 - 11.7)(CA_n + 1)}{2} + 11.7$$

# VITAE

Name : Ahmad Mahboob

Nationality : Pakistani

Date of Birth : 8/11/1990

Email : ahmadz@live.co.uk

Address : KFUPM Graduate Housing, Building # 813, Room # 220

Academic Background : **MS (Petroleum Engineering)**

December, 2016

King Fahd University of Petroleum and Minerals

Dhahran, Saudi Arabia

**B.Sc. (Petroleum Engineering)**

December, 2011

University of Engineering and Technology (UET)

Lahore, Pakistan

Publications

1- Poster presentation “An Experimental Study of Interfacial tension and Contact Angles of CO<sub>2</sub>/Brines/Surfactants/Oil Systems with Dolomite Rock”

at AICHE Meeting 2015, paper number 431445, ISBN:

978-0-8169-1094-6

2- Winner of 2016 SPE-KSA YP&SO Paper Contest

3- Presented “An Experimental Study of Interfacial tension and Contact Angles of CO<sub>2</sub>/Brines/Surfactants/Oil Systems with Dolomite Rock” at YPTS 2016

10- Conference Paper “An Experimental Study of Interfacial tension and Contact Angles of CO<sub>2</sub>/Brines/Surfactants/Oil Systems with Dolomite Rock”

182839-MS SPE 2016

11- Conference Paper “A Rigorous Correlation for Quantitative Prediction of Water Cresting in Multi-Fractured Horizontal Wells” 182778-MS SPE 2016
