I would like to dedicate my thesis work to my beloved parents and teachers.

ACKNOWLEDGMENTS

I would like to express my gratitude to the KFUPM for giving me this opportunity to avail fully funded Master of Science scholarship program in Mechanical Engineering.

It would be my pleasure to thank my advisor Dr. Muhammad Mustafa Kamal for his valuable supervision throughout my thesis. He has always accommodated me for discussing thesis related issues and has provided with simple yet effective suggestions. Along with consistent guidance, he inspired me during the course of this thesis. He has specifically taught me skills to carry out effective literature review and the analysis of results obtained from our research. He also offered several plausible suggestions, based on his precious experience, for the future prospects related to my career.

I am indebtedly thankful to my co-advisor Dr. Mohammed Abdulaziz Mustafa Habib for continuous support during my thesis. I would also like to thank my committee members Dr. Syed Ahmad Mohammad Said, Dr. Ahmet Sahin and Dr. Medhat Ahmed Nemitallah for adding value to my thesis with their valuable suggestions. Especially, Dr. Medhat guided me all the way in the numerical research. It would be my pleasure to mention my gratitude towards Dr. Ahmed Abdelhafez for enriching my thesis especially for providing his valuable insight on data analysis and experimental techniques. I would like to express my gratitude towards my friends, colleagues, seniors and lab attendants for making this thesis work possible for me.

I would also like to thank my family for helping me throughout my life. I have completed my graduate studies because of their consistent love and support.

ABSTRACT

Full Name : Asif Ali

Thesis Title : Static stability and combustion features of $C_3H_8/O_2/CO_2$, $C_3H_8/O_2/N_2$ and $CH_4/H_2/O_2/CO_2$ turbulent premixed flames in a model gas turbine combustor

Major Field : Mechanical Engineering

Date of Degree : March 2020

This thesis work aims at investigating and comparing the macrostructure and stabilization modes of swirl-stabilized premixed oxygen-enriched air-propane ($C_3H_8/O_2/N_2$) and oxy-propane ($C_3H_8/O_2/CO_2$) turbulent flames in a model gas turbine combustor, under similar conditions of equivalence ratio ($\varphi = 0.1 - 1.0$), bulk throat velocity (U_{in}) of 5.2 m/s and oxygen fraction ($OF = 21\% - 70\%$). The constant contours of adiabatic flame temperature (AFT) were plotted with combustor stability maps within the φ - OF domain for both CO_2 and N_2 flames. Nominated flames were captured for studying the effects of AFT on flame stability and structure. The radial and axial temperatures were measured inside the quartz confinement for getting an insight of thermal flow field. It was found for both CO_2 and N_2 flames that the blowout and flashback limits followed constant AFT contours on the stability map. Even the CO_2 and N_2 flames of different OF and φ represented similar structure at identical AFT . While the flames possessing similar OF or φ (resulting in different AFT) exhibited distinct flame macrostructure. This defined the dominance of AFT parameter in controlling the flame dynamics. This finding would be handy for gas turbine designers, manufacturers and operators in retrofitting the existing air-based combustors to the reduced-emissions oxy-fuel combustors.

Large Eddy Simulation (LES) work was also carried out for investigating the combustion and emission characteristics of stoichiometric hydrogen-enriched oxy-methane ($\text{CH}_4/\text{H}_2/\text{O}_2/\text{CO}_2$) flames. The study focused on the effects of hydrogen fraction (HF), oxygen fraction (OF) and inlet bulk velocity (U_{in}) of the combustible mixture on stability and combustion characteristics of the flames. Constant U_{in} of 4.4 m/s, 5.2 m/s and 6.0 m/s were investigated in this analysis. The results indicated that reaction rates are increased with increasing HF and OF , resulting in compact flames. The CO emissions increased from 140 ppm at $HF=20\%$ to 279 ppm at $HF=60\%$, and these emissions increased from 140 ppm at $OF=30\%$ to 594 ppm at $OF=38\%$. The Damköhler number (Da) increases with increasing HF and OF , while it showed declining behavior with increasing U_{in} because of smaller residence time. It was found that the physical parameter (U_{in}) slightly affects the flame kinetics, as compared to the chemical factors (HF and OF). It was also noticed that the role of the OF is more dominant in contrast to HF , and even smaller increments in OF significantly affects the flame dynamics. This finding was reasoned with the increased chemical kinetics due to enhanced concentrations of O atoms, which oxidize fuel species and results in efficient combustion. The reaction rates thus dominate the flame behavior, while turbulence affects only the macrostructure of the flame.

ملخص الرسالة

الاسم الكامل: آصف علي

عنوان الرسالة: الاستقرار السكوني ومميزات الاحتراق للهب المضطرب من نوع $C_3H_8/O_2/CO_2$ و $C_3H_8/O_2/N_2$ و $CH_4/H_2/O_2/CO_2$ الممزوج مسبقاً في غرفة الاحتراق التوربيني الغازي النموذجي

التخصص: الهندسة الميكانيكية

تاريخ الدرجة العلمية: آذار 2020

تهدف هذه الرسالة إلى دراسة ومقارنة أوضاع الهيكل الكلي والاستقرار للهب المضطرب المستقر والممزوج مسبقاً من لهب غني بالأكسجين والمحتوي على بروبان هوائي ($C_3H_8/O_2/N_2$) و لهب محتوى على بروبان مؤكسد ($C_3H_8/O_2/CO_2$) في غرفة الاحتراق التوربيني الغازي النموذجي، تحت نفس الظروف لنسبة التكافؤ ($\phi = 0.1 - 1.0$)، السرعة الكلية عند المدخل (U_{in}) المساوي لـ 5.2 متر/ث، ونسبة محتوى الأكسجين ($70\% - 21\% OF$). لقد تم رسم الخطوط الكفافية (الكنترورية) لدرجة حرارة اللهب الأديباتي (AFT) بخرائط استقرار غرفة الاحتراق ضمن نطاق ال $\phi-OF$ لكل من لهب CO_2 و N_2 . تم رصد كلا النوعين من اللهب لدراسة تأثير ال AFT على استقرار وبنية اللهب. لقد تم رصد درجات الحرارة الشعاعية والمحورية داخل وعاء الكوارتز للوصول إلى فهم مجال التدفق الحراري. وُجد أن حدود النفخ والاتجاع لكل من لهب CO_2 و N_2 قد اتبعت خطوط AFT الكنتورية الثابتة على خريطة الاستقرار، على الرغم من أن لهب CO_2 و N_2 ذوي قيم OF و ϕ مختلفة قد مثلاً بنيتين متماتلتين عند نفس قيم ال AFT . في حين أن اللهب الذي يمتلك قيم متساوية من OF أو ϕ (ناتجة من قيم مختلفة من AFT) قد أظهر بنية لهبية متباينة. هذا بدوره قد حدد مقدار تغلب العامل AFT في التحكم بديناميكية اللهب. هذه النتيجة ستكون مفيدة لمصممي التوربينات الغازية والمصنعين والمشغلين العاملين في إعادة تأهيل المحارق القائمة المعتمدة على الهواء لتصبح محارق معتمدة على وقود الاوكسي منخفضة الانبعاثات. بالإضافة إلى ذلك، فقد تم إجراء محاكاة الدوامة الكبيرة (LES) لدراسة خصائص الاحتراق والانبعاث للهب الميثان المؤكسد ($CH_4/H_2/O_2/CO_2$) ذوالمكونات المتكافئة والغني بالأكسجين. ركزت الدراسة على تأثير نسبة الهيدروجين (HF)، نسبة الأكسجين (OF)، والسرعة الكلية عند المدخل للمزيج القابل للاشتعال على خصائص استقرار واحتراق اللهب. تم فحص قيم ثابتة من ال U_{in} خلال عملية التحليل على النحو التالي، 4.4m/s، 5.2 m/s، 6.0m/s. أشارت النتائج أن سرعات التفاعل قد زادت عند زيادة ال (HF) وال (OF)، مما نتج عنه نيران مضغوطة. بالإضافة إلى ذلك، فإن انبعاثات ال CO قد زاد تركيزها من 140 ppm عند $HF=20\%$ إلى 279 ppm عند $HF=60\%$ ، وأن هذه الانبعاثات قد زاد تركيزها من 140 ppm عند $OF=30\%$ إلى 594 ppm عند $OF=38\%$. لقد لوحظ أن رقم دامكولر (Da - Damköhler number) يزيد عند زيادة ال HF وال OF ، بينما ينخفض هذا الرقم عند زيادة قيمة ال U_{in} بسبب قصر وقت الركود. وقد وجد أن العامل الفيزيائي (U_{in}) يؤثر قليلاً على حركية اللهب، مقارنة بالعوامل الكيميائية (HF و OF). ولوحظ أيضاً أن دور OF أكثر هيمنة، على عكس HF ، وحتى الزيادات الصغيرة في OF تؤثر بشكل كبير على ديناميكيات اللهب. يمكن الاستدلال على هذا الاستنتاج من خلال زيادة الحركية الكيميائية بسبب التركيزات المعززة لذرات O ، والتي تؤكسد أنواع الوقود وتؤدي إلى احتراق فعال. من ذلك يمكن الاستنتاج بأن سرعة التفاعلات هي من يحكم سلوك اللهب، بينما تؤثر درجة الاضطراب على المكونات الكلية للهب فقط.

CHAPTER 1

INTRODUCTION

With advancement in technology and economy, the global power demand is escalating and requires reliable and environmentally friendly sources of energy. According to the International Energy Agency (IEA) expectations, more than 30% of the global energy demand will be increased by 2040 [1]. Due to the improved power density and efficiency, combustion is responsible for majority of the current energy supply and it is likely to play this significant part in foreseeable future. The swift growth in the demands of energy, fossil fuels reserves depletion and hazardous nature of combustion emissions are demanding researchers to look for reliable and cleaner methods of energy conversion [2,3]. So that the available fossil fuels reserves can be utilized as efficiently and cleanly as they could be.

Air is utilized for combustion of fossil fuels in most of the existing combustion applications including gas turbines. Exhaust of fuel oxidized with air comprises mainly of CO_2 , H_2O , O_2 , N_2 , and NO_x . Among these exhaust gases; CO_2 is a greenhouse gas being the reason of ever rising global warming problem. Presently, global energy mix is heavily relying on the fossil fuels for energy harnessing and is projected to remain for several years to come. While CO_2 is a certain product of fossil fuel combustion, with ever increasing stricter regulations on emissions, it becomes necessary to explore ways for its separation and capture. When CO_2 is in a mixture with other exhaust products especially NO_x , it is both expensive and complicated to separate and capture it [4].

1.1 Oxy-fuel Combustion

Oxy-fuel combustion stands out as one of the promising solutions to this problem. When pure O_2 is used as an oxidizer instead of air, the main products of fossil fuel combustion are CO_2 and H_2O . Simple condensation is a cost-economic process, which removes H_2O from exhaust, thereby leaving CO_2 ready for capture. Removal of N_2 , which makes about 79% of air by volume, from the products, causes improvement in the efficiency of treatment equipment, and it also, reduces the size of the hardware. Moreover, the absence of N_2 in reactants reduces the probability of molecular interactions of N_2 and O_2 at elevated temperatures at first, which in turn nearly eliminates the possibility of thermal NO_x formation (via Zeldovich mechanism [5]) in oxy-fuel combustion. Air- and oxygen-based combustion systems, on the opposite way, have significantly varied degrees of freedom, in terms of their stable operation. Air is an abundantly available resource, so it is usually used in higher proportions with the fuel in order to achieve complete combustion in various applications. Lean operation also results in reduced combustion temperatures, thus safeguarding the structural integrity of the combustor. Since pure oxygen is an expensive product in itself, most of the oxy-fuel combustion applications are usually operated at or near stoichiometric conditions. On contrary, in absence of N_2 gas that acts as a third body, absorbing the heat of combustion, this stoichiometric operation of oxy-fuel combustion consequently approaches to higher temperatures. Due to this reason, pure O_2 is diluted with recycled CO_2 by using exhaust gas recirculation (EGR), for reduction of combustion temperature. Oxy-fuel combustion thus, have fuel and O_2/CO_2 oxidizer as its reactants. However, since CO_2 has greater heat capacity and lower thermal diffusivity and chemical dissociation [3,4] on contrary to N_2 , the substitute of N_2 with CO_2 lowers down LFS and

combustion temperatures in oxy-fuel combustion in comparison to air-fuel one [5-8]. Due to this reason, 21% O₂ in O₂/CO₂ oxidizer mixture is not achievable and, therefore, O₂ composition should be more than this composition in the oxidizer mixture for achieving stable flames.

1.2 Lean Premixed Combustion

Fuel and oxidizer mixtures are thoroughly blended before reaching combustor and resulting flames are termed as premixed flames. When this combustion phenomena proceeds below stoichiometric conditions; the fuel is efficiently utilized, and these flames are termed as lean premixed (LPM) flames. With stricter environmental regulations and depleting reservoirs of fossil fuels, it will be one of the significant motivations for the existing LPM air-based combustion customers to switch towards oxy-fuel combustion without any substantial hardware changes. Understanding the behavior of stable flames is essential for switching in between oxidizers. In addition, different fuels have distinct combustion and emission characteristics, and thereby different combustor stability behaviors. This signifies development of a combustor equipped with fuel-flexibility which can utilize various fuels using premixed oxy-combustion technique.

1.3 Oxygen-Enriched Air Combustion

Air, which is about 79% N₂ and 21% O₂ by volume, is being currently used as an oxidizer for majority of the combustion applications. However, the role of oxidant is chemically played by O₂ while N₂ behaves as a stability agent for the combustion process. N₂ carries heat along with it through exhaust from the combustor, resulting in relatively reduced

temperature and therefore decreased thermal efficiency. Most of the thermal processes use elevated proportions of O₂ in air for high temperature applications. Such combustion processes are termed as oxygen-enriched air combustion (OEAC). The O₂ enrichment of air-based combustion results in improved flame characteristics, higher heat transfer efficiency, rising processing rates, enhanced product quality and reduced equipment cost [12] but possesses a disadvantage in terms of increased NO_x emissions. However, these benefits of OEC can turn upside down if combustion system is improperly designed, as further problems originate and may cause non uniform heating, elevated concentrations of pollutants and even burner or refractory damage.

There are generally four primary ways [12] of enhancing combustion process with oxygen: (1) O₂ lancing i.e. adding O₂ in air/fuel flame, (2) premix enrichment or low-level O₂ enrichment i.e. O₂ is injected in the combustor approaching air stream, (3) air-oxy/fuel combustion i.e. burner is provided with air and O₂ separately, (4) oxy/fuel combustion i.e. high purity O₂ replaces air and it is being considered as a favorable prospect of capturing carbon from the exhaust gases [13–15]. The present study utilizes this third and fourth techniques for investigating and comparing the stability and combustion characteristics of propane-based flames.

Low-level O₂ enrichment (21-30% O₂) requires little modifications in burner for permitting its operation. The cases, where small amounts of O₂ enrichment significantly increases the rate of production of the heating process, utilize this low-level O₂ enrichment technique, as it economically saves retrofitting cost of the burner. Existing air/fuel burners require replacement with explicitly designed burners for intermediate (30-90% O₂) and high-level (>90% O₂) oxygen-enrichment cases.

1.4 Oxy-fuel and Air-fuel Combustion - A Comparison

Oxy-fuel combustion results in elevated temperatures reaching to hazardous levels. Unlike air-fuel combustion, oxy-fuel combustion is generally operated under stoichiometric conditions because air is an abundant free of cost resource while burning with pure O_2 is a relatively expensive process. It is therefore recommended to dilute O_2 with exhaust gas, primarily composing of CO_2 and H_2O , in oxy-fuel combustion where H_2O could be easily detached with the help of economic condensation process. The use of CO_2 gas with O_2 as an oxidizer mixture reduces down the combustor temperature. However, while comparing the oxy-fuel combustion to the air-fuel one, the flame characteristics such as mass diffusivity, heat capacity, thermal conductivity and dynamic viscosity are affected with the replacement of N_2 with CO_2 [16–18]. Reaction rates, combustion efficiency and flame speed are reported to be adversely affected with CO_2 presence [19]. The stability and flame characteristics with the O_2/CO_2 oxidizer mixture are therefore different as compared to the O_2/N_2 ones. The combustion characteristics of propane with O_2/N_2 and O_2/CO_2 oxidizer mixtures have rarely been investigated. This information will aid the gas turbine designers and operators in development of oxygen-enriched air-propane and oxy-propane gas turbines.

1.5 Hydrogen Enriched Combustion

The oxidizer mixture of O_2 and CO_2 presents unwelcomed instabilities and varied combustion behavior in contrast to air-based combustion, as discussed [8]. It has been reported that increasing concentrations of CO_2 reduces reaction rates, thereby resulting in poor combustion efficiency and reduced burning velocities [20–22]. Therefore, the mixing

of a higher flame speed fuel with base fuel is advantageous. Hydrogen has been historically used as rocket propellant due to its higher flame speed, and its addition with hydrocarbon fuel results in cleaner flames with wider flammability limits [23]. Hydrogen is being considered as a potential energy carrier because of its range of advantages, as it projects to play a vital role as a fuel additive with natural hydrocarbons in gas turbines and internal combustion engines.

Research community is foreseeing the use of hydrogen-blended fuels as one of the promising alternatives of the natural gas in combined cycle power generation cycles [24–26]. Several studies have shown that hydrogen-enrichment of the conventional fuels considerably reduces soot formation and CO₂ emissions [27,28]. Others have reported wider lean flammability limits and increased laminar flame speed for hydrogen-enriched flames [29–33]. Furthermore, both the average and the instantaneous characteristics of premixed turbulent flames are affected with even very minute addition of hydrogen concentration to the basic fuel [34]. Although widespread investigation has been performed on air-based combustion of hydrogen enriched methane (such as [35]), hydrogen-enrichment of oxy-fuel flame still requires further research to justify its role in a process that is preferably carried out at near stoichiometric conditions.

1.6 Problem Statement

There is scarce understanding of stable combustion zones pertaining to the premixed CO₂-diluted oxy-propane flames (C₃H₈/O₂/CO₂) and oxygen-enriched air-based propane flames (C₃H₈/O₂/N₂). The knowledge of stability and combustion characteristics of these flames will aid gas turbine designers and operators in prospective shift toward oxy-fuel and

enhanced-O₂ combustion. The present work endeavors to fill this gap by investigating the stability and flame macrostructures of propane-based flames.

In addition, the stability of premixed hydrogen-enriched CO₂-diluted oxy-methane (CH₄/H₂/O₂/CO₂) flames have been investigated but there is a shortage of understanding in terms of the influence of oxygen fraction (*OF*) on flame structure and pertaining emissions on these hydrogen-enriched flames. Therefore, this study also incorporates large eddy simulations (LES) for investigating the performance of CH₄/H₂/O₂/CO₂ flames.

1.7 Objectives

The objectives of present thesis work include,

1. Investigation of the stable range of combustion for C₃H₈/O₂/N₂ and C₃H₈/O₂/CO₂ flames for a range of *OF* and equivalence ratio (φ).
2. The characterization of a range of combustible mixture needs to be carried with studying the influence of various parameters.
3. The effects of hydrogen fraction (*HF*), *OF* and bulk throat velocity (U_{in}) on combustion and emission attributes of CH₄/H₂/O₂/CO₂ flames are aimed to be numerically investigated.

1.8 Organization of the work

This thesis work includes eight chapters. It starts from discussing the main topic of the study introduced in Chapter 1, which comprises of basic theories which lay foundation for the formation of basic building blocks. Chapter 2 comprehensively considers the available till-date understanding of targeted area of the present study through literature review.

Chapter 3 presents the experimental and numerical model setup, along with test conditions used for this investigation. Chapter 4 illustrates and analyzes the findings related to the stability and macrostructure of $C_3H_8/O_2/N_2$ and $C_3H_8/O_2/CO_2$ flames. It also encompasses results and discussion on combustion and emission characteristics of $CH_4/H_2/O_2/CO_2$ flames. Chapter 5 sums up the key findings of this investigation with concluding remarks. In the end, Chapter 6 describes the future framework of the present study.

CHAPTER 2

LITERATURE REVIEW

Previous studies on oxy-fuel combustion were majorly inclined towards coal combustion, as it is a carbon rich fuel and burning it alone with oxygen results in increased concentration of waste CO₂, which consequences in increased carbon capture efficiency [36,37]. Majority of these oxy-fuel studies dealt with non-premixed and partially premixed conditions, while influence of swirler has also been included. Tamallah et al. [38] contrasted lean premixed swirl stabilized air and oxygen-based methane flames. Adiabatic flame temperature (*AFT*) of oxy-methane and air-methane combustion was matched by adjusting the dilution ratio in oxy-fuel mixture. Strouhal number's (based upon the flow inlet velocity and the azimuthal spinning frequency of outer recirculation zone) value was reported to be constant, irrespective of the inlet *Re*, at about 0.12 for both the oxygen and air-based flames. It was therefore concluded that *Re* is not the governing parameter for maintaining similar flow conditions in outer recirculation zone; instead, inlet flow velocity of mixture controls it. This finding persuaded to conduct the current experiments at fixed inlet velocity. Tamallah et al. [38] observed that single relationship exists between characteristic flame time (the reciprocal of extinction strain rate) and characteristic flow time (reciprocal of spinning frequency) in both air and oxygen-based flames.

2.1 Effects of Oxygen-enrichment on combustion characteristics

Research on temperature distributions, heating rate, fuel consumption and emissions with changing O₂ concentration from 21-30% was carried out by Wu et al. [39]. They studied

O₂ enrichment effects by using the furnace-temperature fixing and heating tests. They reported that amount of the time required for reaching 1200°C was 46% lesser for 30% O₂, as compared to 21% O₂ enrichment, signifying the enhanced heat transfer rate with increasing O₂ concentrations. During the transition from 21-30% of O₂ concentration, NO_x emissions rose up by about 4.4 times and CO₂ concentrations also showed linear increments. It was also reported that air/fuel mixture with O₂ concentration of 30% consumed 26% lesser fuel as compared to the air/fuel mixture with O₂ concentration of 21%. Merlo et al. [40] studied the role of O₂-enrichment on pollutant emissions and stability of diffusion methane-air swirl stabilized flames. They reported that increasing O₂ concentrations highly encourages CO conversion to CO₂ and more NO_x emissions were formed because of higher temperatures in the combustor. Moreover, it was reported that even with the low O₂ enrichment proportions, the flame stability got increased. Daood et al. [41] used coal air-staged combustion for studying the effects of O₂ enrichment on carbon burnouts and NO reduction. They reported that O₂ enrichment improves the carbon burnouts. In addition to it, at 31% of staging the experiments revealed that there was approximately 7% NO reduction with 28% of O₂ enrichment, whereas 35% NO reduction with 35% of O₂ enrichment, revealing an increase in NO reduction with greater concentrations of O₂. Tan et al. [42] studied enriched O₂ and O₂/CO₂ combustion in a down-fired vertical combustor. They reported that higher temperatures of flame and elevated concentrations of O₂ resulted in very high levels of NO_x. However, O₂/CO₂ flames suppressed NO_x formation because of the unavailability of N₂ and very minute level of NO_x was traced due to the air leakage at the fan. Horbaniuc et al. [43] studied OEC effects in large steam boilers. They reported an increase of about 2-5% in the boiler efficiency,

because of high temperatures of flue gases. This higher mean logarithmic temperatures within the heat exchangers cause reduction of the heat transfer surfaces. Qiu and Hayden [44] explored membrane separation for air-enrichment and investigated the impact of OEC on natural gas flames in porous ceramic radiant burners. Polymer membranes were utilized for passive production of O₂-enriched air, and O₂ was enriched from 21% to 28%. Their experimental results revealed that O₂ enrichment of air of 28% reduces about 22% of the natural gas consumption. Lambert et al. [45] studied OEC impacts on steam methane reforming using membrane separation technique for air-enrichment. They reported that an optimum O₂ enrichment of air is 29% for steam methane reforming.

2.2 Flame Speed dependence on Adiabatic Flame Temperature

While air-based fossil fuel combustion has already been utilized in the industry and focus is now being shifted towards oxy-fuel combustion and O₂ enriched air-fuel for cleaner and efficient energy conversion. As review has defined examples of different fuels burnt with excessive O₂ concentration air using different combustion techniques, all these studies have followed similar characteristic that increasing ϕ of reacting mixture increases both flame speed *LFS* and *AFT*. According to Kaskan [46], the maximum *LFS* of propane-air flame was reached at $\phi = 1.1$ and drops for all other richer and leaner mixtures. Kaskan [46] and Van Maaren et al. [47] after conducting investigations on various fuels presented a relationship between *AFT* and *LFS* as $\log(LFS) \propto 1/AFT$. Moreover, this relation was found to be valid for both liquid [48] and gaseous [49] fuels. It was reported that preheating the reactants mixture increases *LFS*. The dilution of mixture with H₂O, argon, CO₂, helium, or N₂ decreases the *AFT* and therefore *LFS* is reduced. Due to the importance of *AFT* in

controlling flame dynamics, the present study investigates the influence of *AFT* on CO₂ and N₂ based premixed propane flames.

Shroll et al. [50] studied the dynamic stability features of oxy-methane flames. They used *OF* for controlling *AFT*. Although the burning velocities of both air and oxygen-based flames are quite different for a specific *AFT* value, but still both of these flames were similar in the fact that *AFT* of the reactant mixture controls the movement from one stability point to the other. Since turbulent flame geometry is a strong function of *AFT*, they reinforced this finding by showing high-speed images of the comparable vortex breakdown modes, which was representing similar turbulent flame geometries. Kutne et al. [51] used swirl stabilized model combustor used for gas turbines for comparing the partially premixed oxygen and air-based methane flames. They considered range of 0.5-1 for φ and 20%-40% for *OF*. It was concluded that the flame characteristics are strong function of the *OF*, while φ affects them only slightly. This finding influenced the investigation of the *OF* effects on CH₄/H₂/O₂/CO₂ flames. Moreover, they reported that inner recirculation zone of the oxy-flames was existing further downstream in contrast to the air-based ones, representing the inferior stability of oxy-flames. This comparison of the flame characteristics for air and oxy-propane flames have been rarely investigated, as per the literature review and motivated experimental investigation of the flame stability and macrostructure of C₃H₈/O₂/CO₂ and C₃H₈/O₂/N₂ flames in this thesis work.

2.3 Propane-based Combustion

Propane C₃H₈ has been used as vehicle fuel, propellant, refrigerant and petrochemical feedstock. It is a key component of Liquefied Petroleum Gas (LPG) and its utility for heating and cooking purposes is significant. Although its concentration in natural gas is

minor yet it is sensitive to overall combustion performance. With growing energy demands, depleting fossil fuel reserves and endeavors for cleaner environment, the knowledge of combustion performance of CO₂ and N₂ based propane mixture cannot be neglected. Chu et al. [52] investigated O₂ enrichment effects on soot formation with diffusion propane flames. Their analysis conveyed that O₂ enrichment increases combustion temperature and also broadens up the soot formation region, resulting in increased volume fraction of soot particles. Abubakar et al. [53] studied C₃H₈/O₂/CO₂ diffusion flames and reported that as CO₂ dilution increases 40%, the flame shape changes from jet like shape to lifted V-structured shape. The characteristics of premixed propane flame have been rarely investigated and the current study therefore focuses at investigating the stability of premixed C₃H₈/O₂/CO₂ and C₃H₈/O₂/N₂ flames.

Due to varied combustion behavior of different fuels along with their subsequent different emissions characteristics, the stability performance of flames changes with variations in reactant loading conditions. Therefore, the design and development of fuel-flexible burners is necessitated so that, different flames with different loading conditions under lean premixed oxy-fuel and O₂-enriched air-fuel combustion conditions can have sustainable and stable flames. The combustion behavior of propane-based flames needs further investigation, especially in terms of flame stability and combustion characteristics, as it has been rarely studied so far. This study aims to fill this gap and investigate the combustion performance of these flames in a dry low emission (DLE) lean premixed (LPM) swirl stabilized model combustor for giving an insight to designers and operators of its stable flame behavior. The advantages of O₂-enriched air-propane and oxy-propane combustion can be harnessed by having fuel-flexible gas turbines with minimal retrofitting. In this

study, the stability and structure of these flames are investigated at fixed mixture inlet velocity of 5.2 m/s for DLE model combustor of gas turbines, ranging the equivalence ratio from 0.1 to 1.0 and oxygen fraction from 21% to 70%.

2.4 Effects of Hydrogen-Enrichment on Oxy-Methane Flames

Researchers are aiming for carbon-free fuels for mitigating the hazardous effects of greenhouse gases on our environment. Hydrogen has been used as a rocket-propellant and has the potential of efficient and environmentally friendly energy conversion. One portion of the present work comprises on the effects of HF , OF and U_{in} on the combustion phenomena of $CH_4/H_2/O_2/CO_2$ flames using LES.

Hu et al. [54] and Sarli et al. [55] examined the influence of hydrogen-enrichment on laminar flame speed (LFS) and reported a linear correlation between them. Tang et al. [56] also reported that hydrogen-enrichment of fuel blend enhances both unstretched laminar flame propagation and flame speed. Moreover, they noticed that dependence of these properties is more notable at higher hydrogen fractions (HF_s) in the fuel blend. Sankaran and Im [57] and Hu et al. [54] reported that augmented molecular diffusivity of H_2 and enhanced formation of radicals (such as H, O and OH) are main reasons behind improved LFS of hydrogen-enriched flames. Nakahara et al. [58] observed a monotonic increase in turbulent flame speed (TFS) with hydrogen-enrichment in a lean combustible mixture. An analogous behavior has been described by Halter et al. [34] for TFS of hydrogen-enriched premixed methane/air flames. They also showed that hydrogen-enrichment enhances the turbulent flame speed (S_T) more readily than the corresponding LFS , thereby resulting in an overall higher combustion intensity (TFS/FS). Danielle et al. [59,60] also confirmed

these findings and stated that hydrogen-enrichment slightly increases the flame front curvature distribution, thus augmenting the small scale flame wrinkling which consequently yields higher *TFS*. The chemical behavior of CO₂ in lean to stoichiometric CH₄/H₂/O₂/CO₂ mixtures were investigated by Liu et al. [61]. They identified significant reduction in *LFS* with elevating concentrations of CO₂ in oxidizer mixture. They also reported reaction between atomic hydrogen and CO₂ as a mitigation factor for dominant radicals (i.e. H, O and OH), which subsequently retards the *LFS*. Schefer [62] experimentally studied the stable behavior of hydrogen-enriched flames. He reported that the lean blowout (*LBO*) limit was maximum with stoichiometric conditions and it was reduced for both rich and lean mixtures. In addition, *LBO* limit was reduced by nearly 15% and OH mole fraction was increased by almost 20% with hydrogen addition of about 20% (by vol.) in the fuel mixture. Although hydrogen addition decreases *AFT* of the flame but due to its higher combustibility, higher reaction zone temperatures are reported for the flames with higher *HF*s. Fast expansion of reaction zone results due to elevated temperature and therefore inhibits cooler recirculation flow [23].

Cheng and Littlejohn [63] studied the combustion features of pure hydrogen-dilution of air and H₂-N₂ mixture in a laboratory scale low swirl injector (LSI) for implementation in integrated gasification combined cycle (IGCC) gas turbines. With variable bulk velocities in the system, the study found that *LBO* limit is reached nearly at a fixed equivalence ratio (φ) of 0.17 indicating the independency of *LBO* limit with varying Reynolds number (*Re*). Damköhler number (*Da*) was found to be another parameter which successfully predicts the *LBO* limit. In addition, an interesting finding explained that different combinations of CH₄/CO/H₂ concentrations reach *LBO* at a constant Damköhler number of 0.4. Similar

conclusion was reported in one of our previous studies on the current combustor model of gas turbine [64]. It was found that *LBO* limit occurs at fixed *AFT*. This indicates that *AFT* is a more appropriate factor choice than φ or oxygen fraction (*OF*) for quantification of static stability map of the combustor.

Suliman et al. [29] investigated role of hydrogen-enrichment and inlet velocity of the reactants premixed CO₂ diluted oxy-methane flames. It was reported that the hydrogen addition results in reducing the size of flames; representing improvement in reaction chemical kinetics. Stable range of combustion for these flames were identified by quantifying flashback and blowout extinction limits.

Nemitallah et al. [65] carried out numerical and experimental investigation for studying influence of hydrogen-enrichment and inlet velocity of the premixed hydrogen enriched CO₂ diluted oxy-methane flames. They reported that chemical kinetics reaction rate dominates the reaction and turbulence does not alter the macrostructure of the flame. They further reported that hydrogen addition results in wider operability range and improved heat release rates.

The thesis work aims at experimental and numerical investigation of flame behavior and attributes, as well as the emission features of the premixed CO₂-diluted hydrogen-enriched oxy-fuel flames in a premixed dry low emission (*DLE*) swirl combustor – a topic of emerging interest that has been rarely investigated. The investigation was performed under stoichiometric combustion conditions to make perfect use of oxygen in order to translate oxy-combustion in an inexpensively feasible process. The study explores the flame behavior for a range of *HF*, *OF* and bulk throat velocity (U_{in}) of the mixture. The role of

the OF has not yet been studied for hydrogen-enriched flames, as per the review and knowledge of authors. The present investigation sheds light on influence of the OF on premixed $CH_4/H_2/O_2/CO_2$ flames, which also was not addressed in the investigations of Suliman et al [29] and Nemitallah et al [65]. Furthermore, emissions characteristics owing to changes in HF , OF and U_{in} are reported in the current study, which makes this investigation novel. The current measurements and subsequent analysis provide useful information for minimizing the adaptability and retrofitting issues of existing air-fuel gas turbines to reduced emission hydrogen-enriched oxy-fuel turbines.

CHAPTER 3

EXPERIMENTAL AND NUMERICAL MODEL

3.1 Experimental Setup for $C_3H_8/O_2/CO_2$ and $C_3H_8/O_2/N_2$ flames

3.1.1 Combustor Model Specifications

The LPM DLE swirl stabilized premixed fuel-flexible model gas turbine combustor was used for examining premixed $C_3H_8/O_2/CO_2$ and $C_3H_8/O_2/N_2$ flames for clean and efficient power production. The schematic diagram of combustor setup, with the combustor headend at the top is shown in Figure 2.1. The power density range of operational gas turbines is usually $3.5\text{-}20\text{ MW/m}^3/\text{bar}$ and therefore, this experimental gas turbine combustor follows the same. Static stability of the O_2 enriched flames was found with the help of two flame extinction limits i.e. blowout and flashback limits. Experiments were performed with non-preheated atmospheric pressure containing reactants with fixed inlet bulk velocity.

A 55° geometric swirler was installed on the combustor for providing swirl effect to the premixed reactants of controlled composition. After swirler, flow of reactants was accelerated as it passed through a converging-diverging throat insert with diameter of 2.0 cm placed in the immediate downstream of swirler. For reduction in swirl loss, insert gave gradual convergence of 30° to the flow and then for the prevention of its sudden expansion downstream, 45° divergence was induced. A quartz tube was placed at the top of combustor headend for confining O_2 enriched flames from atmospheric air.

Figure 2.1 - Model gas turbine combustor schematic used for experiments.

The flow velocity at the throat was balanced by the flame velocity for achieving stable flame behavior, as it has been defined previously as an important characteristic for achieving stable flames [66]. Flashback can also be resulted because of vortex breakdown so a conical solid bluff body was fitted in the centerline of the burner.

Below the swirler inlet, a premixed reactant mixture was composed by injecting air, C_3H_8 and O_2 gases in mixing pipe of 1.0 m length and 2.0-inch diameter. Aalborg Inc. thermal

mass flow controllers of $\pm 0.5\%$ full-scale accuracy, were used for controlling the gas flow rates, with an uncertainty of $\pm 0.4\%$ in OF and ± 0.02 in φ . The mixing plenum of an aspect ratio (length/diameter) of about 20 was used for ensuring maximum premixing of the reactants in the pipe. The oxidizer gases i.e. air and O_2 were injected from opposite sides, while fuel gas i.e. C_3H_8 was added by a tube placed in the center of pipe. This tube was packed from its top and 12 radial holes arranged in three consecutive planes were used for diffusing fuel in the mixing pipe. These holes of fuel inlet were aligned with oxidizer inlets of air and O_2 gases. Although, direct measurement of degree of premixing of the reactants was not carried out but a test was conducted for evaluating the effectiveness of premixing. This test comprised on different stable flames of varied compositions. From the reference position shown in Figure 2.1, the axial location of fuel inlet holes present in the tube was varied from +100 mm to -25 mm. Corresponding aspect ratio was changed from 18.5 to 20.5. The change in holes location shown no discernible effects on flame color, noise, shape and size, which implied perfect premixing of the reactant mixture. All of the investigated flames possessed a constant inlet velocity of 5.2 m/s for entire examined compositions of the premixed reactants. For safety reasons, an emergency shut-off valve was installed in fuel line for promptly cutting down fuel supply on reaching flashback limit. The changes in the visual flame appearance indicated the changes in the operating parameters during experiments. Flame shape analysis was carried out with photographic flame images taken by a 24 MP camera of 1600 ISO, 5.6 f-stop and 1/60-s shutter speed features.

A thermocouple of 1.0 mm junction diameter and of R-type (PtRh13%-Pt) from Omega was incorporated for measuring local mean temperature inside quartz confinement. At each

location, the average temperature is measured with multiple readings with the help of thermocouple probe, which is connected to a data logger and a computer. A traverse mechanism is incorporated for precise axial and radial movements of thermocouple probe, which enters in the confinement from top of the tube.

The model by Brohez et al. [67] was, then, used for correction of the radiation errors to the surroundings. Measurements of axial (through centerline of the combustor) and radial (at heights of 10.0 cm and 20.0 cm from the combustor throat) temperature distributions for selected flames were performed. For further details of experimental procedure and setup, reader is referred to one of the previous studies of the Authors [68].

3.1.2 Test Conditions and Governing Equations

The premixed $C_3H_8/O_2/CO_2$ and $C_3H_8/O_2/N_2$ flames are investigated at constant inlet velocity in present study. Considerable differences in the macrostructure and operability limits of the flames are expected due to the involvement of different diluents (CO_2 and N_2). The terms of “bulk throat velocity” and “bulk Re ” refer the quantities of all participating reactants in $C_3H_8/O_2/CO_2$ and $C_3H_8/O_2/N_2$ flames and not $C_3H_8+O_2$ alone.

The Authors [69] have examined $CH_4/O_2/CO_2$ flames previously and a thorough description of approach for keeping the inlet velocity fixed at 5.2 m/s has been provided. The following species flow rates are found by using this generalized approach for a diluent X, which is either N_2 or CO_2 .

$$\dot{m}_{C_3H_8} = 44 \left(\frac{pAv_a}{R_u T} \right) \left(1 + \frac{2}{OF\phi} \right)^{-1} \quad (3.1.1)$$

$$\dot{m}_{O_2} = 64 \left(\frac{pAv_a}{R_u T} \right) \left(\varphi + \frac{2}{OF} \right)^{-1} \quad (3.1.2)$$

$$\dot{m}_X = 2M_X \left(\frac{pAv_a}{R_u T} \right) \left(\frac{1-OF}{\varphi OF+2} \right) \quad (3.1.3)$$

Therefore,

$$\dot{m}_{N_2} = 56 \left(\frac{pAv_a}{R_u T} \right) \left(\frac{1-OF}{\varphi OF+2} \right) \quad (3.1.3a)$$

And

$$\dot{m}_{CO_2} = 88 \left(\frac{pAv_a}{R_u T} \right) \left(\frac{1-OF}{\varphi OF+2} \right) \quad (3.1.3b)$$

Where φ and OF are examined over the ranges of 0.1-1.0 and 21%-70% respectively.

It is important to mention about eq. 3.1.1 that the diluent (X) properties do not affect the propane gas mass flow rate $\dot{m}_{C_3H_8}$; i.e. the similar amount of fuel is consumed for both test sets of common OF and φ . In addition, oxygen-enrichment of pure air flow is performed for producing desired O_2/N_2 diluted oxidizer mixture with any OF . The required air flow rate is calculated as follows, by using \dot{m}_{N_2} from eq. 3.1.3a and the fact that by mass, air consists of 76.7% nitrogen

$$\dot{m}_{Air} = \frac{\dot{m}_{N_2}}{0.767} \quad (3.1.4)$$

Depending on eq. 3.1.2, 3.1.3a, and 3.1.4, enriched oxygen flow rate is determined as

$$\dot{m}_{enO_2} = \dot{m}_{N_2} + \dot{m}_{O_2} - \dot{m}_{Air} \quad (3.1.5)$$

The dynamic viscosity of bulk reactant mixture is calculated as follows [70]

$$\mu_{mix} = \frac{\sum y_i \mu_i \sqrt{M_i}}{\sum y_i \sqrt{M_i}} \quad (3.1.6)$$

Likewise, its bulk density is calculated by using the following formula

$$\rho_{mix} = \frac{P \sum \dot{m}_i}{R_u T \sum (\dot{m}_i / M_i)} \quad (3.1.7)$$

The Reynolds number at the throat of the burner is calculated as

$$Re = vD\rho_{mix}/\mu_{mix} \quad (3.1.8)$$

The exhaust gas composition and AFT are dependent on both OF and φ of the reactant mixture. Moreover, with the help of tabulated enthalpies of formation for C_3H_8 , N_2 and O_2 and sensible (temperature dependent) enthalpies of CO_2 , O_2 , and H_2O [71], the thermodynamic analysis is carried out for calculating AFT .

3.1.3 Experimental Procedure

With fixed bulk inlet velocity, mass flow rates of individual reactants were changed and mutually adjusted according to a specific data point (with definite OF and φ). OF ranged from 21% to 70% while φ was fluctuated from 0.1 to 1.0. For every OF representing a unique flame, following procedure was followed for investigating blowout and flashback extinction boundaries.

- (a) As a first step, flame was ignited at a safe ignition point, away from both flashback and blowout extinction limits.
- (b) For reaching the required data point indicated by distinct OF and φ , mass flow rates of individual reactants were adjusted. For a fixed OF , richer φ was sought if flashback extinction limit was required and similarly leaner φ was hunted for the flame to extinct

with blowout. Higher audible noise and jet like flame shape attached to the throat of the combustor were observed to be the indication that flame is near its flashback limit.

Weaker lifted flames represented the vicinity of blowout extinction limit.

(c) At a specified OF , φ was made cautiously leaner and flame started to become weak and lifting up from the throat surface, until it reached till blowout limit and this specific combination of the OF and φ was noted as a blowout extinction point.

(d) After it, stable flame was ignited and richer φ was sought. As flame started to emit audible noise, gradual movement was made with smaller careful transitions especially near the flashback limit. At the point of flashback limit, audible noise reached its maximum level accompanied by an explosion and flame flashed back to the burner throat. This specific φ was noted with OF as a flashback extinction point.

(e) Steps from (a) to (e) were repeated again for the complete range of the OF . Static stability map was plotted for both blowout and flashback limits, by connecting the highlighted blowout φ point of different OF domain and similarly by joining the nominated flashback φ points.

3.2 Numerical Model Setup of CH₄/H₂/O₂/CO₂ flames

The numerical simulations were performed with CH₄/H₂ fuel and O₂/CO₂ oxidizer mixtures at atmospheric pressure and stoichiometric condition. The power density of model combustor mimics the operation range from 3.5 to 20 MW/m³/bar, which is typical of operational gas turbines. Numerical simulations of the test cases are performed for a range of HF (from 20% to 60% by vol.), OF (from 30% to 38% (by vol.) and U_{in} (from 4.4 m/s to 6.0 m/s).

3.2.1 Equations of Conservation

The incorporated mathematical model solves the species transport equation and conservation equations of mass, momentum and energy using large eddy simulation (*LES*) model for scalar variables within three-dimensional (*3D*) region representing the model gas turbine combustor. Commercial software package of ANSYS-Fluent 19.2 was utilized for carrying out simulations. Heat transfer, emission characteristics, and flow regime of CH₄/H₂/O₂/CO₂ flames were forecasted by simultaneously solving the elliptic equations in 3D domain. Species transport equation and conservation of mass, momentum, and energy equations are based on the following general equation [72]:

$$\frac{\partial}{\partial x_j} (\bar{\rho} \bar{U}_j \phi + \bar{\rho} \bar{u}_j \bar{\phi}) = \frac{\partial}{\partial x_j} \left[\Gamma_\phi \frac{\partial \phi}{\partial x_j} \right] + \rho \bar{S}_\phi \quad (3.2.1)$$

where ϕ and $\bar{\phi}$ represent Reynolds average and fluctuating components of dependent variable, respectively, u_j is the velocity component in J direction, Γ_ϕ is diffusion component, whereas S_ϕ represents source term.

3.2.2 Radiation Model

Discrete ordinate (*DO*) model was incorporated for solving radiation heat transfer equation such that with every five energy iterations there is one radiative iteration. *DO* model thicknesses has been recommended for modeling oxy-fuel combustion [73] and it is valid for wide range of optical. The absorption coefficient, which is verified over a broad range of operating conditions of gaseous mixture, was calculated with the weighted sum of grey gas model (*WSGGM*) [74,75].

3.2.3 Turbulence Model

Large eddies represent the characteristic length of mean flow, whereas small eddies dissipate the turbulence kinetic energy, and jointly they approximate turbulence in the flow. In this study, turbulence was solved by the LES modeling technique, where small eddies were filtered out. Low-pass filtering operation was considered by utilizing the following equation for a quantity [65]:

$$\bar{\varphi}(x, t) = \int G(r, x)\varphi(x - r, t)dr \quad (3.2.2)$$

This equation solves integration for the entire domain. The scale of the resolved eddies is determined by filter function, G . Following forms of general equations are yielded using continuity, Navier-Stokes equations, and filtering function:

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x_i}(\rho \bar{u}_i) = 0 \quad (3.2.3)$$

$$\frac{\partial}{\partial t}(\rho \bar{u}_i) + \frac{\partial}{\partial x_j}(\rho \bar{u}_i \bar{u}_j) = \frac{\partial}{\partial x_j} \left(\mu \frac{\partial \sigma_{ij}}{\partial x_j} \right) - \frac{\partial \bar{p}}{\partial x_i} - \frac{\partial \tau_{ij}}{\partial x_j} \quad (3.2.4)$$

where σ_{ij} represents the stress tensor (because of the molecular viscosity), defined by:

$$\sigma_{ij} \equiv \left[\mu \left(\frac{\partial \bar{u}_i}{\partial x_j} + \frac{\partial \bar{u}_j}{\partial x_i} \right) \right] - \frac{2}{3} \mu \frac{\partial \bar{u}_i}{\partial x_j} \delta_{ij} \quad (3.2.5)$$

The subgrid-scale stress τ_{ij} is given by:

$$\tau_{ij} \equiv \rho \overline{u_i u_j} - \rho \bar{u}_i \bar{u}_j \quad (3.2.6)$$

Filtering operation results in subgrid-scale stresses, which involve modeling. Isotropic part of the subgrid-scale stress and filtered static pressure terms are therefore merged and modeling of deviator part is carried out by using turbulent viscosity:

$$\tau_{ij} = -2\mu_t \bar{S}_{ij} \quad (3.2.7)$$

where μ_t and \bar{S}_{ij} are the turbulent viscosity and rate of strain tensor, respectively. Wall-Adapting Local Eddy-viscosity (WALE) model was used for solving the turbulent viscosity, and is given by:

$$\mu_t = \rho L_s^2 \frac{(S_{ij}^d S_{ji}^d)^{3/2}}{(\bar{S}_{ij} \bar{S}_{ji})^{5/2} + (S_{ij}^d S_{ji}^d)^{5/4}} \quad (3.2.8)$$

where L_s symbolizes mixing length for subgrid-scale.

Both L_s and S_{ij}^d are given as:

$$L_s = \min(\kappa d, C_w V^{1/3}) \quad (3.2.9)$$

$$S_{ij}^d = \frac{1}{2} (\bar{g}_{ij}^2 \bar{g}_{ji}^2) - \frac{1}{3} \delta_{ij} \bar{g}_{kk}^2 \quad (3.2.10)$$

where κ is denotes von Karman constant. WALE constant is given by C_w , d represents distance to closest wall, and V is volume of computational cell. \bar{g}_{ij} is defined as:

$$\bar{g}_{ij} = \frac{\partial \bar{u}_i}{\partial x_j} \quad (3.2.11)$$

3.2.4 Reaction Kinetics Model

Fully premixed combustion case for hydrogen-enriched oxy-methane simulations was accommodated with modified partially premixed combustion model. The transport equations for the mean mixture fraction \bar{f} , the mixture fraction variance $\overline{f'^2}$ and the mean reaction progress variable \bar{c} were computed for obtaining additional scalar variables. The reaction progress variable is defined as the mass fraction of specific species in the mixture and possesses a value of 1.0 for burnt gas mixture and zero for unburnt mixture. Mixture fraction is given as:

$$f = \frac{sY_{fu} - Y_{ox} + Y_{ox,0}}{sY_{fu,1} + Y_{ox,0}} \quad (3.2.12)$$

where Y represents the mass fraction with Y_{fu} and Y_{ox} symbolize the mass fractions of fuel and oxidizer. Subscripts 0 and 1 refer to the inlet streams of oxidizer and fuel, respectively, while s represents oxidizer to fuel ratio. The probability density function and progress variable are computed with the distinct mixture fraction and the density weighted average scalars such as species fraction and temperature are computed based on following equation:

$$\bar{\phi} = \bar{c} \int_0^1 \phi_b(f) p(f) df + (1 - \bar{c}) \int_0^1 \phi_u(f) p(f) df \quad (3.2.13)$$

where u and b denote unburnt and burnt mixtures, respectively.

Reaction progress variable, c , is described as a function of mass fraction of product species and is given by:

$$c = \left(\frac{\sum_{i=1}^n Y_i}{\sum_{i=1}^n Y_{i,ad}} \right) \quad (3.2.14)$$

where subscripts i and ad represent the product and the complete combustion species, respectively.

Following correlation was used for estimating the flame thickness:

$$\delta = \frac{\lambda_u}{\rho_u c_p S_L} \quad (3.2.15)$$

where ρ_u and λ_u represent thermal density and conductivity, respectively.

The ratio indicating the rate of reaction to the rate of diffusion is given by Damköhler number:

$$Da = \frac{(l_t/u')}{(\delta/S_L)} \quad (3.2.16)$$

where l_t indicates the integral length scale and u' represents the root mean square (*RMS*) of velocity fluctuation.

3.2.5 Boundary Conditions

For reducing the computational time, only an axis-symmetric quadrant of symmetric modeled reactor was considered for all the simulations as shown in Figure 2.2. After performing a mesh independency study, 40,000 finite volume cells were selected. This model was also used in one of the investigations carried by the authors [65]. Fine meshes were created near burner region whereas cruder meshes were generated in outlet and near outlet zone. Various compositions of $\text{CH}_4/\text{H}_2/\text{O}_2/\text{CO}_2$ with constant yet distinct throat velocity (U_{in}) were introduced in the combustor through the inlet. Tangential and axial components of flow were used for introducing a swirl flow of 0.98 swirl number [65].

Fluctuating velocity was solved by incorporating vortex method algorithm. According to set values of equivalence ratio and mixture composition, calculations were performed for the mean mixture fraction using the modified partially premixed model.

At the combustor wall, mixed thermal boundary condition was defined with both external radiation and convection heat transfer mechanisms, as well as convective heat transfer coefficient of $20 \text{ W/m}^2/\text{K}$ and free stream temperature of 300 K . The semi-transparent boundary type was set to the 6.0 mm wall thickness. The radiation heat transfer through the quartz confinement was estimated using non-gray band model with 4.0 wavelength bands. The tangential components of swirling flow were taken care with periodic boundary conditions, which were assigned to both symmetric faces of the considered quadrant portion of the combustor. All simulations were carried out at fixed equivalence ratio of 1.0 (stoichiometric condition) with varying OF , HF and U_{in} .

CHAPTER 4

RESULTS AND DISCUSSION

3.1 Experimental Results of $C_3H_8/O_2/N_2$ and $C_3H_8/O_2/CO_2$ flames

3.1.1 Combustor Stability Maps

Oxygen and Nitrogen possess comparable properties i.e. nearly similar heat capacities and densities. It is thus expected that changes in the oxygen fraction (OF) of the diluted O_2/N_2 oxidizer mixture would not considerably affect the oxidizer properties. In contrast, CO_2 contains substantially different properties. It is therefore anticipated that OF would play an important role in oxy-fuel flames especially in affecting the important combustion parameters like adiabatic flame temperature (AFT), as it is vital for the premixed flames analyses and it will be discussed in this results section.

The stability of the premixed oxygen-enriched air-propane ($C_3H_8/O_2/N_2$) and carbon dioxide diluted oxy-propane ($C_3H_8/O_2/CO_2$) flames is quantified for DLE combustor of gas turbine over ranges of equivalence ratio (0.1-1) and oxygen fraction (21%-70%), at fixed inlet velocity of 5.2 m/s. Stability maps (blowout and flashback limits) are presented against the constant AFT curves. Figure 3.1 illustrates the obtained stability maps for the N_2 (top) and CO_2 (bottom) flames. The error bars have been added to each data point for experimental uncertainty analysis.

Figure 3.1 - Combustor stability maps of $C_3H_8/O_2/N_2$ flames (top) and $C_3H_8/O_2/CO_2$ flames (bottom) along with constant AFT curves, with a throughout fixed inlet velocity of 5.2 m/s.

For each OF , blowout point is designated by circular symbol, whereas flashback point is portrayed with diamond symbol. The exponential fits were observed for adequately representing blowout and flashback limits with R^2 values of 0.9991 and 0.9978, respectively for N_2 flames and 0.9966 and 0.9989, respectively for CO_2 flames. The area in between the fit lines represents the stable zone of combustion, while the areas below and above are the blowout and flashback zones respectively. For a one-to-one comparison, the colored backgrounds of constant AFT contours are presented at the same scale.

A primary observation of this study indicates that the blowout and flashback limits for both CO_2 and N_2 based flames follow the same AFT (Figure 3.1), for this specific case of constant inlet velocity of the premixed reactants. The slight deviation from AFT contour observed in CO_2 blowout and flashback limits is attributed to the error associating the simplified estimation of AFT ; CO_2 flames have significantly more effluent CO_2 than N_2 flames; see Figure 3.2. If CO_2 dissociation was accounted for in AFT , the blowout and flashback limits would have followed a constant- AFT contour. Note that the mole fraction of effluent CO_2 increases along the flashback and blowout limits in direction of lower OF , and this region is exactly where the AFT error maximizes.

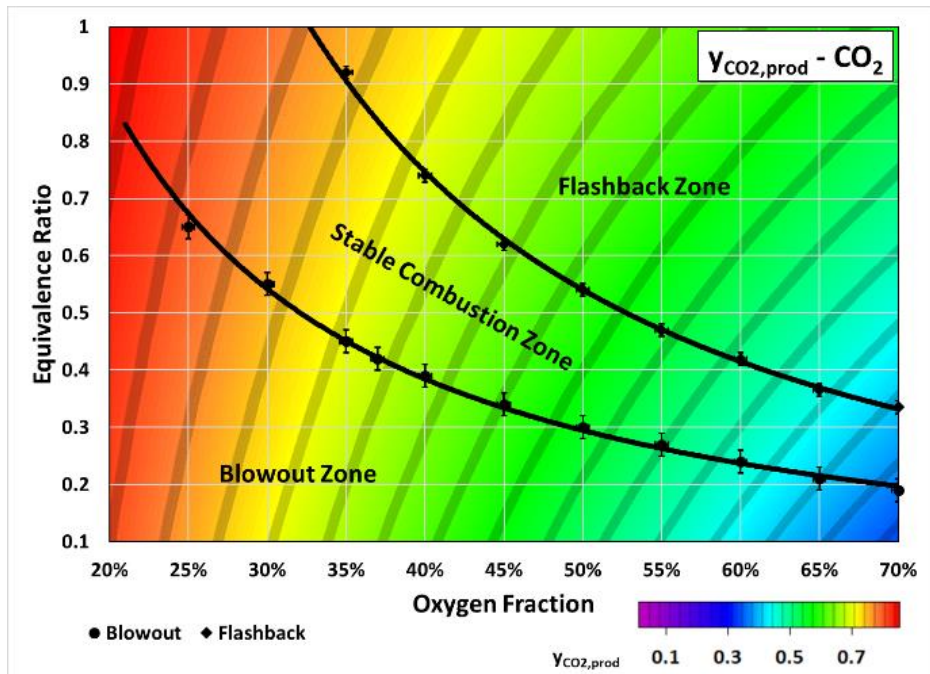

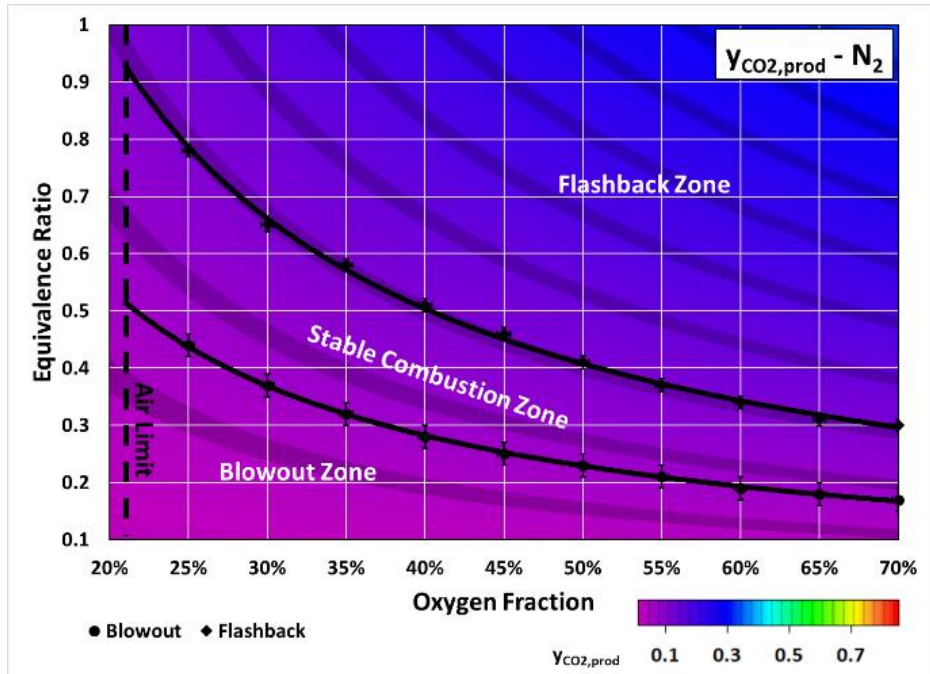

Figure 3.2 - Static stability of the combustor plotted against the curves of N_2 mole fraction (top) and CO_2 mole fraction (bottom).

The stability maps of the CO₂ and N₂ flames are plotted in Figure 3.3 for comparison. It indicates two preliminary observations. First, CO₂ flames possess steeper slopes of constant *AFT* contours $[(\frac{\partial \varphi}{\partial OF}) AFT]$. It indicates that *AFT* of oxy-propane flames is highly influenced by *OF*, as mentioned above. Second, the *AFT* of CO₂ flames is lower than that of N₂, for any specific set of *OF* and φ . The smaller heat capacity of N₂ in comparison to CO₂ is the reason for both observations. The static stability limits correlate well with *AFT* for both CO₂ and N₂ flames and it is a unique outcome for C₃H₈ flames and agrees with the previous findings for CH₄ flames [76].

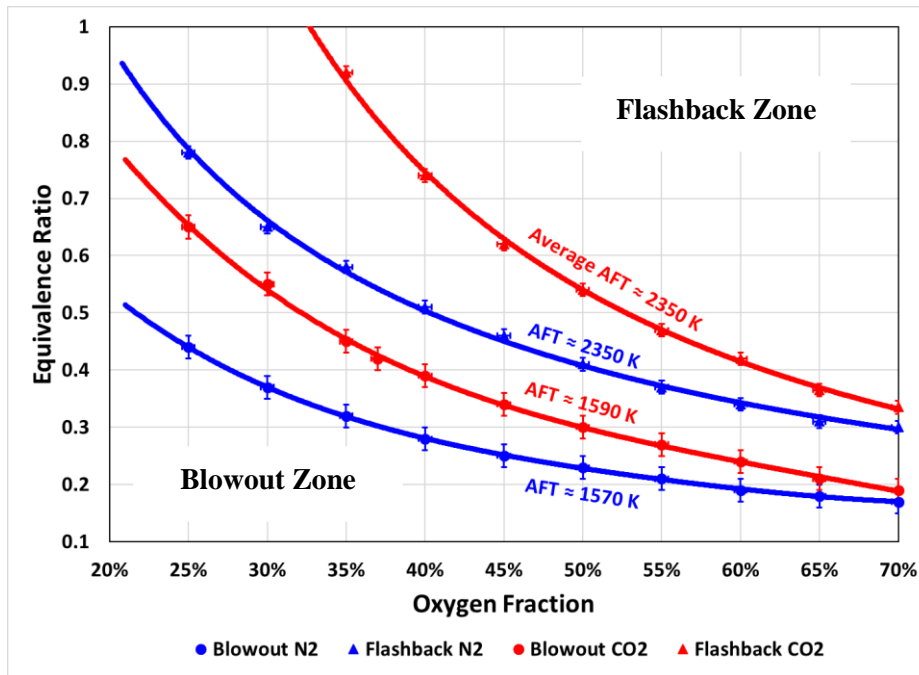

Figure 3.3 - Comparison of the stability maps of C₃H₈/O₂/CO₂ and C₃H₈/O₂/N₂ flames.

Some remarkable observations are:

- The blowout limits for both CO₂ and N₂ flames were reached at ~1580 K
- The flashback limits for both CO₂ and N₂ flames were reached at ~2350 K

- At the same φ , the flashback of the N_2 flames occurred at lower OF as compared to CO_2 flames. CO_2 flames have relatively retarded chemical kinetics and require more oxygen for flashback. This finding consolidates with the ones found by Jerzak and Kuźnia [77].
- The stability of CO_2 and N_2 flames start behaving identically as OF is increased. It is because of reduced concentrations of CO_2 and N_2 in the oxidizer mixture at higher OF .

These constant AFT contours are having distinct slopes for the blowout and flashback curves of CO_2 and N_2 flames (Figure 3.1) yet both the blowout and flashback limits of each type of flame reached at the same AFT (Figure 3.3). The authors have recently reported the fixed AFT following of the flashback limits for $CH_4/O_2/N_2$ [76] and $CH_4/O_2/CO_2$ [69] flames. The novelty of present work lies in the finding that both $C_3H_8/O_2/CO_2$ and $C_3H_8/O_2/N_2$ flames follow constant AFT curve not only for the flashback limit, but also for the blowout one. From these observations, it is found that the dominant role of AFT in controlling the chemical kinetics of the reaction is universal. For the cases of fixed inlet velocity (constant cold flow condition), the reaction kinetics mainly control the flame extinction limits. A subtle balance was observed during experiments, between flame speed and flow velocity at points of extinction. Use of constant bulk throat velocity indicates that each extinction limit is reached at a fixed flame speed. It further confirms prevailing nature of chemical kinetics in flame extinction phenomenon. Along with other parameters, the flame speed also directly depends upon the AFT and it becomes a reason for both types (CO_2 and N_2) of flames to extinct at constant AFT .

It can be inferred based on this analysis that the design and operation of premixed oxy-propane combustors are recommended to be dependent on *AFT*, notably for high and medium load configurations. This practice is also being followed in the current gas turbine markets for manufacturing the advanced LPM air-fuel gas combustors. The equivalence ratio is used for controlling the flame temperatures in air-fuel combustors, but the gas turbine manufacturers base their design, operation and evaluation of the combustors on the flame temperature (because of aforementioned reason) and not on the equivalence ratio. Constant inlet flow velocity is another common methodology in existing LPM air-fuel gas turbines and therefore the present study recommends the use of *AFT* as the controlling parameter for oxy-fuel combustors. During operations, the practice of constant pressure-drop across the combustor is maintained for achieving constant bulk throat velocity. This practice supports a safety margin for flashback event to occur in the combustor.

The flame extinction limits, in terms of blowout and flashback boundaries, of the investigated $C_3H_8/O_2/CO_2$ flames are compared in Figure 3.4 with the ones belonging to the $CH_4/O_2/CO_2$ flames obtained in a previous investigation [64] on identical combustor. It is observed that both the flashback and the blowout extinction limits of the methane flames are reached at higher φ in contrast to those of propane flames for the same *OF* in diluted oxidizer mixture. Since *AFT* of propane is higher (roughly about 50-200 K) than that of methane for the same *OF* and φ , this difference in *AFT* shifts the stability limits of propane to lower φ , as compared to methane, for a given *OF*, because the propane flame is naturally hotter. Moreover, the blowout curves of both mixtures meet at an *OF* and φ of about 70% and 0.2 respectively, whereas the flashback curves coincide at an *OF* and φ of about 37% and 1.0, respectively. At these two set points, both CO_2 diluted oxygen-based

methane and propane flames would have, correspondingly, common blowout and flashback set points. As OF is higher and φ is relatively lower in the common blowout set point, the shift between the lower stability curves of methane and propane diminishes due to leaner mixture condition. Under such lean condition, the flow rate is high enough to blowout the flame regardless the fuel type. Similarly, as OF is smaller and φ is relatively larger in the common flashback point, the richer condition of the mixture contracts this shift between the two flames in the upper stability curve. Under such condition, the reactivity of the mixture is high enough resulting in flame flashback regardless of the fuel type. Further increase in equivalence ratio will convert the combustion to the rich burning zone, which is not preferred for gas turbine applications. In addition, it is observed that the propane flames have wider flame stability region than methane flames, and both zones narrow down towards larger OF and smaller φ . Even narrower stable flame region for oxy-propane flames than oxy-methane flames were obtained at higher OF and lower φ . It can be concluded that oxy-propane flames are more stable at decreased OF and elevated φ , whereas, oxy-methane flames are more stable at enhanced OF and reduced φ .

For ensuring the prominent influence of AFT in dictating the reaction kinetics of investigated flames, the static stability maps are mapped against curves of fixed Re (Figure 3.5). The effect of difference in density of oxygen as compared to N_2 and CO_2 is evidenced in Re maps. The slopes of Re contours $[(\frac{\partial \varphi}{\partial OF}) Re]$. For the CO_2 map are considerably steeper as compared to N_2 one, demonstrating the domination of the OF over the oxy-fuel Re map, as it was previously observed with the AFT . The higher density of CO_2 attributes towards the steeper slopes of Re contours. Although the N_2 map appears to coincide with Re contours, no correlation is observed for CO_2 flames, which proves that AFT is the

primary controlling parameter, not Re . One of the previous studies of the authors [78] on coaxial non-premixed flames revealed that the structure and the stability of $\text{CH}_4/\text{O}_2/\text{CO}_2$ and $\text{CH}_4/\text{O}_2/\text{N}_2$ flames were affected with Re of oxidizer mixture. The Re maps were therefore plotted in present study for investigating the role of Re on flame stabilization.

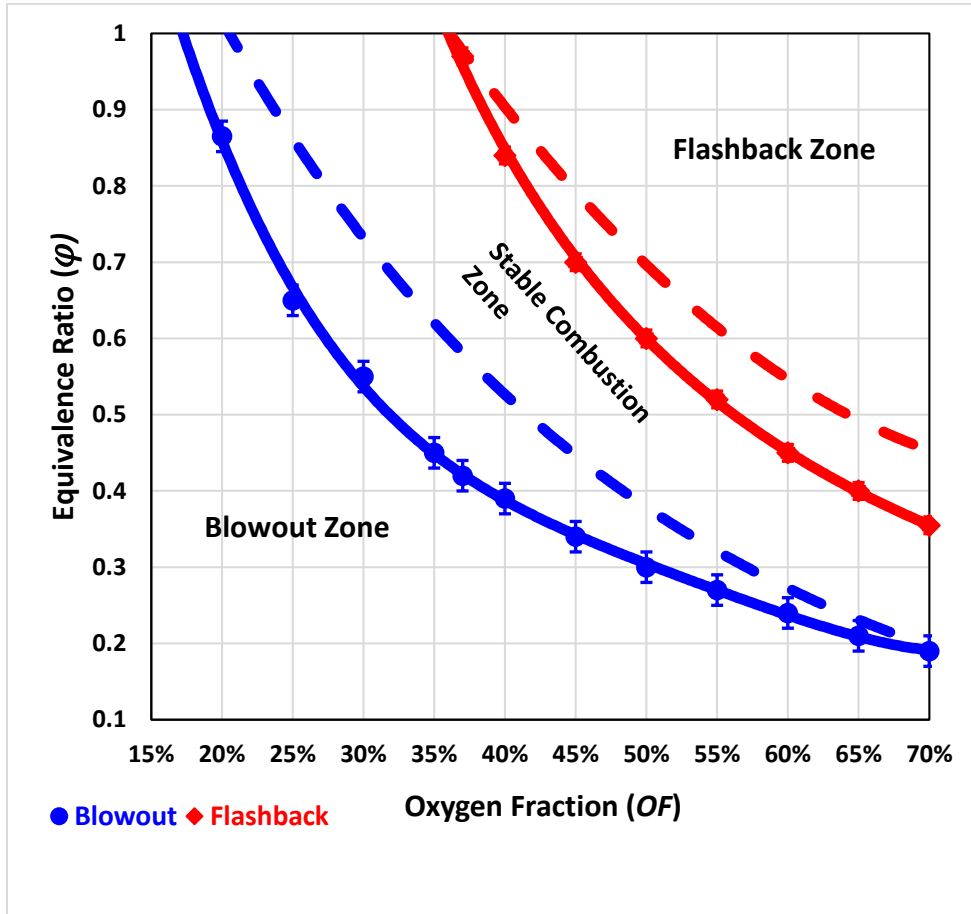

Figure 3.4 - Comparison of static flame extinction limits of $\text{C}_3\text{H}_8/\text{O}_2/\text{CO}_2$ and $\text{CH}_4/\text{O}_2/\text{CO}_2$ flames on identical premixed swirl combustor. The dashed line curves represent the limits for the methane flames, while the solid lines represent the limits for the propane flames.

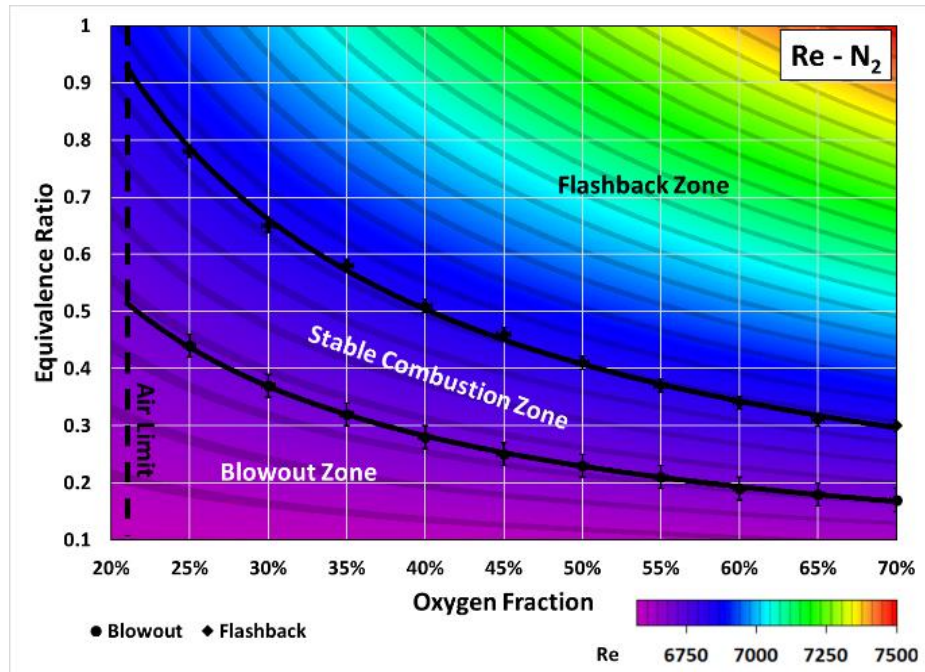

Figure 3.5 - Static stability maps quantifying the blowout and flashback limits at constant bulk throat velocity along with constant Re curves for $C_3H_8/O_2/N_2$ flames (top) and $C_3H_8/O_2/CO_2$ flames (bottom).

3.1.2 Flame Structure Analysis based on *AFT*

The role of *AFT* in controlling the chemical kinetics of the reaction has been discussed above in terms of flame stability. In this section, the response of *AFT* on flame structure is investigated. Figure 3.6 represents the effect of φ on flame macrostructure at constant *OF* = 60%. As expected, increasing φ results in increased flame strength. With the enhancement in φ , tall weak flame changes its shape to the spread-out one initially and then transitions to compact cup-shaped flame for both type of investigated flames. This shift in the flame structure is because of the increased reaction kinetics with superior φ . Despite the different φ values in each *AFT* group, CO₂ and N₂ flames of similar *AFT* have nearly indistinguishable structures, which is a unique learning for the C₃H₈ flames. It validates the dominance of *AFT* in controlling the chemical kinetics of the reaction.

For further exploring the effect of constant *AFT*, different flames irrespective of the type (N₂ or CO₂), φ and *OF* were imaged at *AFT* = 2135 K, as shown in Figure 3.7. It is observed that keeping *AFT* constant results in identical structures for both CO₂ and N₂ flames, which agrees with previous findings for CH₄ flames [76]. Minor changes are observed within the CO₂ flames because of the error associated with the simplified estimation of *AFT*; CO₂ flames have more effluent CO₂ than N₂ flames, as was observed in Figure 3.2. If CO₂ dissociation were accounted for in *AFT*, identical CO₂ flames would have been observed. Again, despite the significantly different φ values at each *OF*, CO₂ and N₂ flames have nearly identical structures, because they have the same *AFT*. This finding is novel for C₃H₈ flames. As CO₂ possesses improved heat capacity as compared to N₂, rise in φ of CO₂ flame to match *AFT* at the same *OF* is just a penalty to be paid to overcome its higher heat capacity.

Figure 3.6 - Effect of ϕ on flame structure at constant $OF = 60\%$

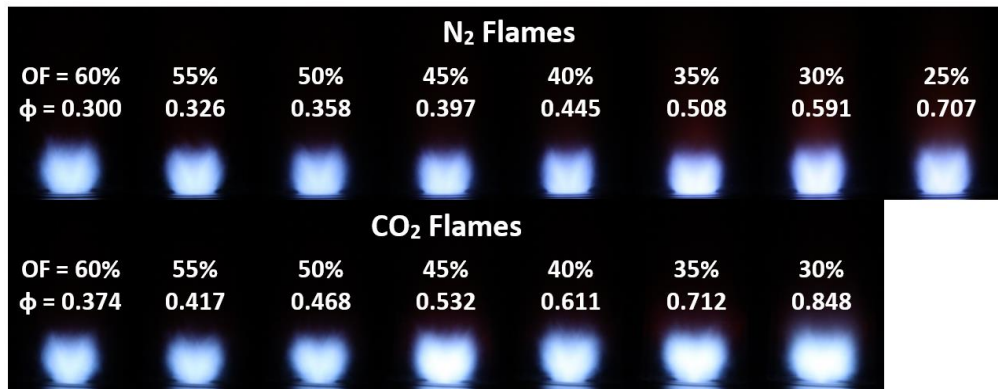

Figure 3.7 - Effect of maintaining constant AFT on flame structure. All CO₂ and N₂ flames have $AFT = 2135$ K

Flame images pertaining to the similar ϕ and OF but different AFT are also captured, as shown in Figure 3.8. It is noticed that switching from N₂ to CO₂ reduces the AFT , as expected, due to superior heat capacity of CO₂. In addition to the negative impact of CO₂ on reaction kinetics, The lower AFT results in deteriorated flame strength. This figure (i.e.

Figure 3.8) plus the two previous figures (i.e. Figure 3.6 and Figure 3.7) prove that *AFT* plays a decisive role in controlling flame structure. Matching φ or *OF* does not result in identical flames but matching *AFT* does, which is the novel finding of the presented study.

Figure 3.8 - N₂ and CO₂ flames of the identical *OF* and φ but different *AFT*

For further analyzing the flame macrostructure and stabilization, flame images are captured as φ is reduced at a fixed *OF*, from near flashback extinction limit to the vicinity of blowout one. The value of φ is noted as flame macrostructure significantly changes. These notable φ values are then indicated on the stability maps of CO₂ and N₂ flames (Figure 3.9). Near the flashback region, the flames (red-bordered) are compact, indicating higher reaction kinetics and dominance of inner recirculation zone (*IRZ*). As φ value is decreased, the flame spreads out (yellow-bordered). A further bit of drop in φ results in the flame starting to lift-up from the base of the combustor (green-bordered). The outer recirculation zone

(*ORZ*) starts to compete with *IRZ* thus resulting in flame lift-up. With further reduction in φ , the macrostructure of the flame finally transitions itself into a conical shape (blue-bordered), indicating the dominance of *ORZ* on the flame structure. In transition of flame macrostructure from compact flames to tall conical ones, reduction in flame noise is also observed during the experiments. Furthermore, with lower *OF* in CO₂ flames, the transition from red-bordered flame to the yellow-bordered one resulted after substantially decreasing the φ value. It is because of elevated heat capacity possessing CO₂ concentrations at reduced *OF*. Moreover, *AFT* of each macrostructure for CO₂ flame is higher as compared to N₂ flame, also due to elevated heat capacity of CO₂.

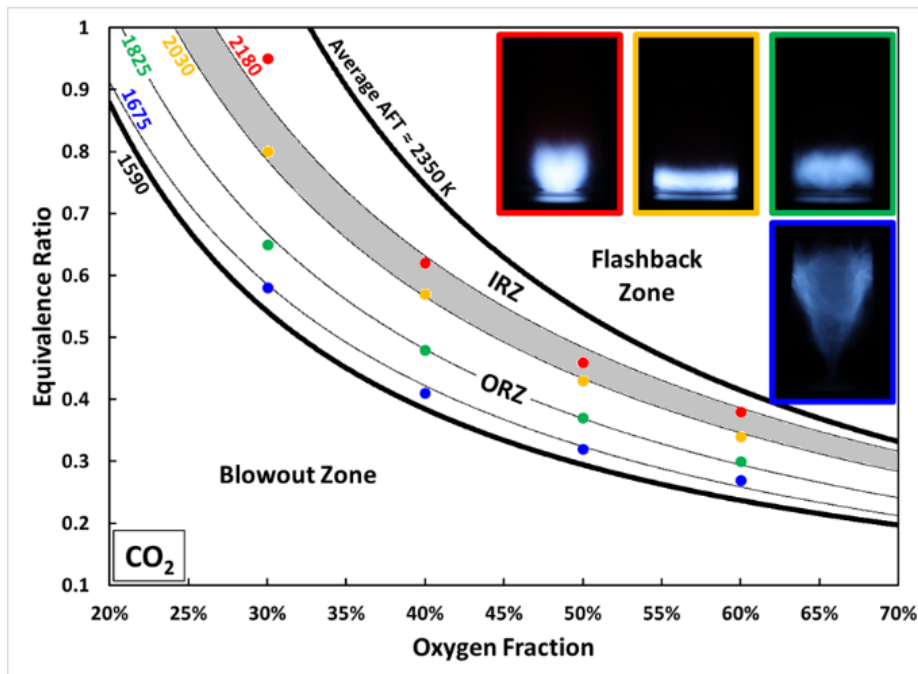

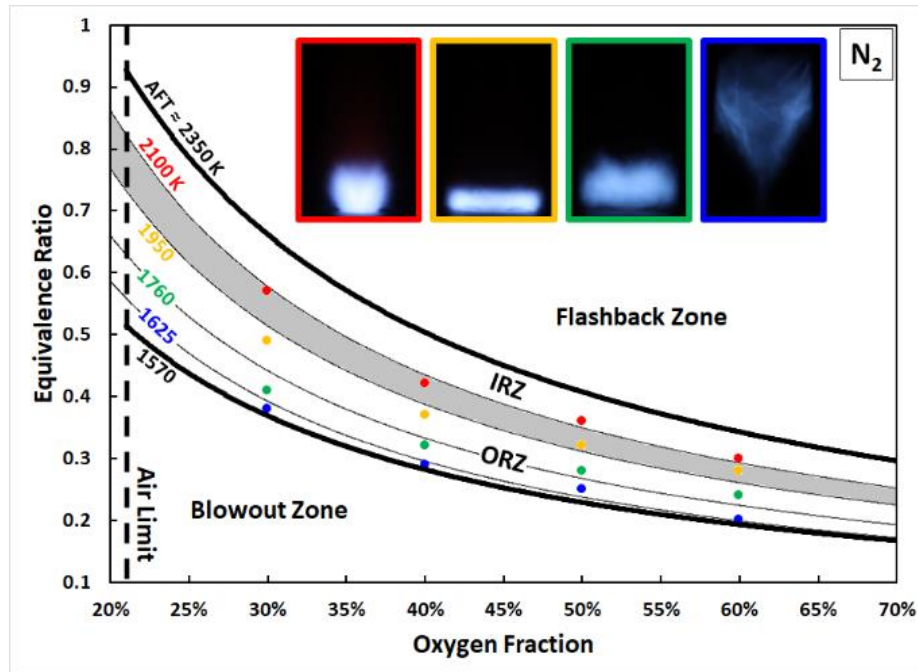

Figure 3.9 - Transition from IRZ to ORZ stabilization in N_2 (top) and CO_2 (bottom) flames.

The outcomes of this investigation trigger the recommendation of designing and operating the prospective combustor of oxy-propane gas turbine dependent on *AFT* and not dilution

ratio or percent exhaust recirculation. *AFT* can easily be estimated for any given set of operating conditions. The stabilization modes and shapes of the stable oxy-propane flames may be clearly deduced based on the information of *AFT* alone. Thus, it is recommended to design the heat shields of combustor headend to be based on *AFT* and its information is also useful in predicting the interaction of adjacent flames, along with the resulting instabilities, in the multi-premixed combustors.

4.1.3 Characterization of Flame Temperature

At different locations, the temperature of $C_3H_8/O_2/CO_2$ flames was measured inside the quartz confinement to further explore the relationship between *AFT* and flame structure. For oxy-fuel combustion conditions, the flame temperature measurements may aid the validation of numerical models. Table 4.1 refers the operating conditions of flames A and B for which local mean temperatures were measured, whereas Figure 3.10 displays their respective flame shapes. The temperature measurements were performed in reference to the axial distance, Z (cm). A bottom reference value of $Z = 0$ cm was assigned to the base of quartz confinement i.e. the exit plane of the burner divergent section and a top value of $Z = 30$ cm was allocated to the exit plane of the quartz confinement. Figure 3.11 represents centerline axial temperature distribution of selected flames from above the flame structure, $Z = 10$ cm to $Z = 21$ cm. Since both flames are having nearly similar *AFT* value, the temperature profiles of both flames also show similar trends. It should also be noted from Table 4.1 that although *AFT* of both flames is nearly equal but the combination of ϕ and OF is quite different. Figure 3.11 also shows that the measured temperatures are slightly different from the theoretical *AFT*, with flame B having a bit higher temperature than flame A at every axial location. It was noticed while testing different flames that the noise coming

out of the quartz tube gets stronger as AFT of the flame increases. Figure 3.10 shows that flame shape is strongly dependent on AFT , as flames A and B present similar plume shape. As φ and OF conditions of both flames are quite different but because of similar AFT only, the flame shapes become similar. Such findings reinforce the role of AFT as the main controlling parameter of flame structure and stability.

Table 4.1: Test conditions of temperature measurements.

Flame number	OF	φ	AFT (K)
A	60%	0.39	2195
B	30%	0.89	2202

Figure 3.10 - Flame images as listed in Table 4.1

Figure 3.11 - Axial centerline temperature distributions for flames A (circular data points) and B (rectangular data points), with $Z = 0$ cm representing the base of the combustor

Due to combustion dynamics, flames cannot be considered as slug flow reactors. Therefore, the radial temperature profiles of the different flames were also measured at two axial locations, $Z = 21$ cm and $Z = 10$ cm, and the outcomes are illustrated for better understanding of the flame structure in Figure 3.12 and Figure 3.13, respectively. Both the flames show decreasing temperatures at locations radially away from the plume. The temperatures shown in Figure 3.12, axially away from the flame, are lower than those in the vicinity of the flame core as displayed in Figure 3.13. The temperature profiles in two figures infer the two-dimensional nature of the flow field. Because of the existence of an inner recirculation zone (*IRZ*), the maximum temperatures values are not located at the centerline of the combustor. Figure 3.12 indicates maximum temperature at a radial distance of 0.5-1.0 cm, while Figure 3.13 reports it at radial distance of 1.0-1.5 cm. The difference here indicates the presence of local *IRZ* of relatively larger size in near exit location of the burner and then gradually decreasing towards the downstream along axial

direction. This recirculation zone is more dominant and thus visible in weaker flames (see CO_2 and N_2 flames at $AFT = 1735$ K in Figure 3.6) as compared to the stronger ones.

Figure 3.12 - Radial temperature distributions for flames A (circular data points) and B (rectangular data points) at $Z = 21$ cm

Figure 3.13 - Radial temperature distributions for flames A (circular data points) and B (rectangular data points) at $Z = 10$ cm

4.2 Simulation Results of CH₄/H₂/O₂/CO₂ flames

4.2.1 Structure and Stability of CH₄/H₂/O₂/CO₂ flames

Flame shape visualization is an important part of analysis for harnessing thorough understanding of flame characteristics. The assessment of different flame shapes also provides insight on flame extinction mechanisms. Figure 3.14 compares natural luminosity images with the numerically generated flame shapes represented as the contours of OH radicals.

Figure 3.14a considers the effect of varying *HF* on the flame shape. For smaller fractions of hydrogen (*HF*=40%) in the fuel mixture, flame possesses a spread-out shape, while for higher hydrogen fractions (*HF*=60%), flame becomes compact and perturbed indicating improved reactivity of the mixture with hydrogen-enrichment. This finding is in agreement with previous investigations reporting enhanced laminar flame speeds as a result of hydrogen-enrichment [79,80]. Higher OH concentrations are observed in numerical flame shape with increasing hydrogen fraction (*HF*=60%), indicating improved reactivity of the mixture. The dark zone below the flame and besides the burner wall in the experimental flame shapes is a representation of the quenching effect. In the *ORZ*, no reaction occurs and there is also some cooling effect near the wall, resulting in local quenching.

Figure 3.14b reveals the consequence of varying *OF* on flame shape. Experimental images indicate brighter and compact flame with increased *OF*, signifying the enhanced reactivity of the combustible mixture due to oxygen-enrichment. The availability of more oxidizer to the fuel results in greater concentrations of reactive species, thus accelerating the chemistry. Similarly, the numerical flame shapes also show that the OH concentration

increases significantly at higher fractions of oxygen ($OF = 38\%$) in the oxidizer mixture. Figure 3.14c explores the effect of bulk throat velocity on the reactivity of combustible mixture by analyzing the flame shape. It is observed that low bulk velocities ($U_{in}=4.4$ m/s) result in strong flame as compared to the higher bulk velocity ($U_{in}=6.0$ m/s). It can be ascribed to consequent increase in residence time for the radicals to interact and react with other chemical species, and thus leading to relatively complete combustion at reduced bulk velocity. Numerical flame shapes also confirm this effect by exhibiting higher OH concentration at reduced velocity. In all the three comparisons shown in Figure 3.14, numerical findings are in agreement with experimental flame shapes, which validates the numerical code used for these simulations.

In order to study flow-flame interactions in the current test cases, the numerical data is further explored by mapping the velocity vectors over static temperature contours as shown in Figure 3.15. The creation of both outer recirculation zone (ORZ) and inner recirculation zone (IRZ) characterizes overall features of turbulent reacting flow field. Figure 3.15a compares the influence of HF on the temperature and flow fields. At lower hydrogen fraction ($HF=40\%$), a large primary eddy (PE) is observed in the downstream (centered at $Z/D=0.6$) preceded by a small recirculation zone slightly upstream of it indicating an impending smaller secondary eddy (SE). With increasing hydrogen concentrations ($HF=60\%$), PE is formed rotating clockwise in the downstream (centered at $Z/D=0.2$) while two SEs are created upstream of it, rotating in opposite direction to each other. The creation of eddies enhances the turbulent-induced mixing, and thus improves the flow reactivity.

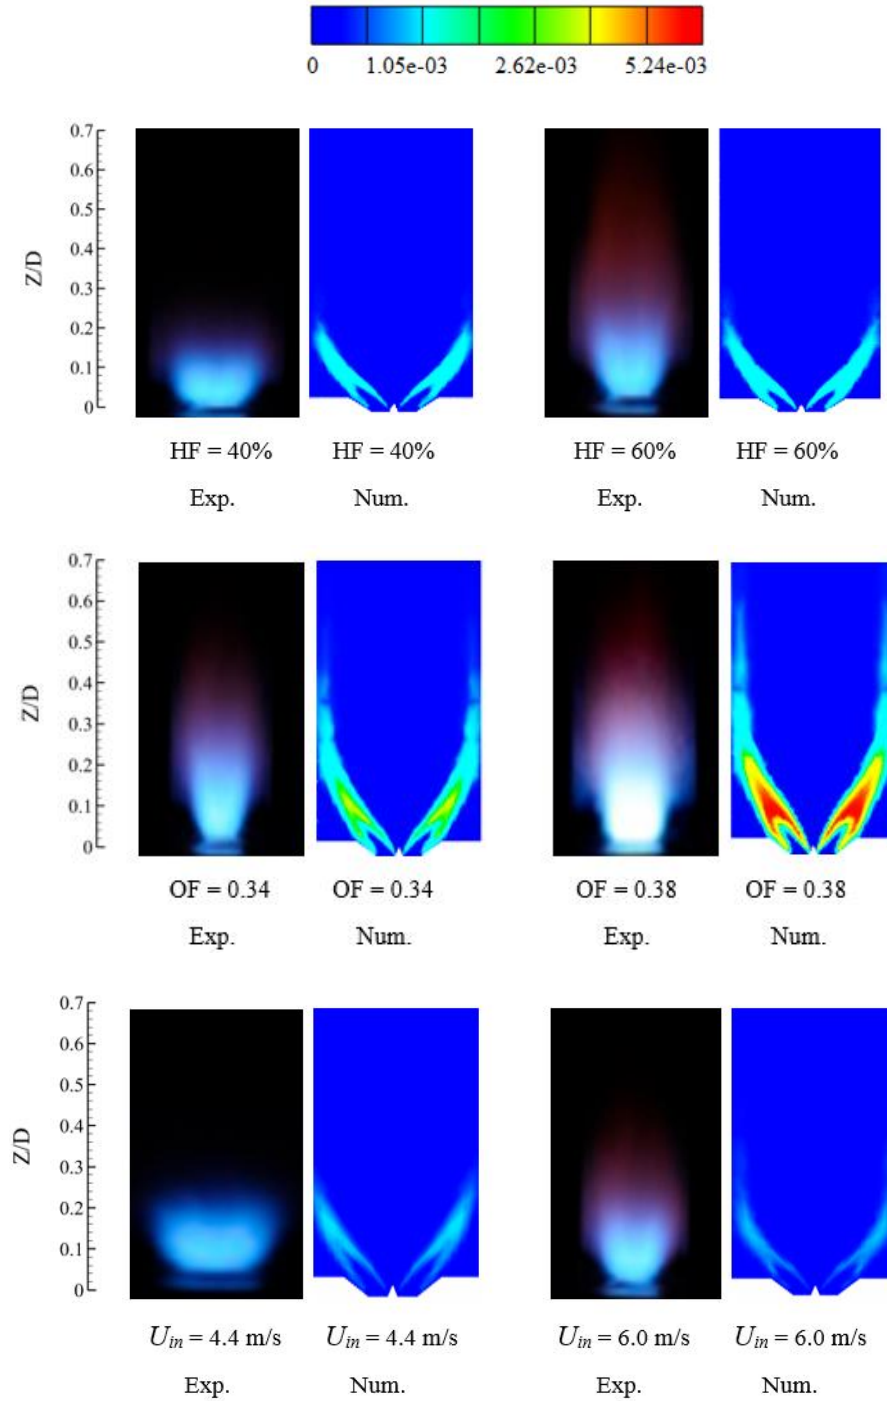

Figure 3.14 - Experimental (images taken with high-speed camera) and numerical (OH contour plots) flame structure comparison under stoichiometric condition at varying: hydrogen fractions at $U_{in}=5.2 \text{ m/s}$ (top), oxygen fractions at $U_{in}=5.2 \text{ m/s}$ (middle), and bulk throat velocities at $HF=20\%$ and $OF=30\%$ (bottom)

Figure 3.15b indicates the role of the OF on thermal structure of flame. Increasing OF results in elevated temperatures because of the enhanced availability of O radicals in the combustible mixture. The temperature, for all cases, approaches about 2300 K in the upstream region but at the combustor exit it scales back to normal values, which is appropriate and reliable for the operations of turbine blades. This interaction of radicals with combustible mixture further enhances reactivity as several eddies are formed. At lower oxygen concentration ($OF=34\%$), a PE appears to be rotating counterclockwise, followed by the opposite direction rotation of a SE . Far upstream, another smaller SE can be seen rotating in the clockwise direction. At $OF=38\%$, the secondary eddies breakdown into several smaller counter-rotating eddies towards downstream, indicating enhanced flame-vortex interactions driven by turbulence-induced coarse mixing. Overall, increasing hydrogen and/or oxygen concentration enhances the reaction rates and thus results in strong and compact flames, as also witnessed in experimental flame shapes as shown in Figure 3.14a and Figure 3.14b.

Figure 3.15c represents physical effects of the bulk throat velocity on the reactant mixture. At lower inlet velocity ($U_{in}=4.4$ m/s), reactant species get more residence time to react with each other [81] and one PE and one SE are formed, both rotating in opposite directions. Whereas, at enhanced inlet velocity ($U_{in}=6.0$ m/s), only one PE is observed rotating in the counterclockwise direction, indicating reduced reactivity of the mixture. In all the three cases of varying HF , OF , and U_{in} , a smaller ORZ is formed at the bottom corner of the reactor, which largely remains unaffected most probably due to its farther location from the flame. Suliman et al. [29] carried out experiments for investigating the flame stability at bulk throat velocity of 6.0 m/s. They have reported flame static stability map versus the

curves of fixed AFT , as shown in Figure 3.16. The temperatures indicated by the simulation of the present study are also validated from his experimental work, as stable flame with $HF=20\%$, $OF=30\%$ and $U_{in}=6.0$ m/s possesses maximum temperature of about 2400 K for both the results reported by Suliman et al. [29] and the present study.

Vorticity is an adequate representation of the tendency of rotation of the flow field which is also directly related to the formation of turbulent eddies. Figure 3.17 represents the magnitude of vorticity contours for different mixture compositions. The region between the inner and outer shear layers indicate dominant reaction zone in the form of stabilized flame. The inner shear layer thickens up with increase in HF , as shown in Figure 3.17a. It is because of the higher vorticity levels in the vicinity of the center of the combustor. Similarly, vorticity increases with increasing OF with increased inner shear layer thickness (Figure 3.17b). Vorticity has high magnitude with increased bulk throat velocity case, as shown in Figure 3.17c, but the length of the inner and the outer shear layers decreases with augmentation in the bulk throat velocity. The dominance of ORZ owing to increased velocity ($U_{in}=6.0$ m/s) might be its possible reason, at which the outer shear layer extends itself and flame, therefore, stabilizes at the corner region of the combustor.

Figure 3.15 - Calculated velocity vectors mapped over temperature (in kelvins) contours under stoichiometric condition with varying: (a) hydrogen fractions at $U_{in}=5.2$ m/s, (b) oxygen fractions at $U_{in}=5.2$ m/s, and (c) bulk throat velocities at $HF=20\%$ and $OF=30\%$

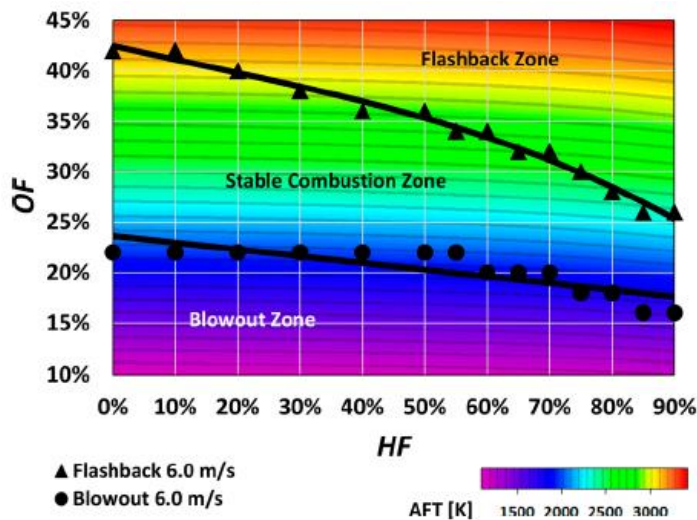

Figure 3.16 - Stability map quantified with blowout and flashback limits at $U_{in}=6.0$ m/s [29]

Figure 3.17 - Calculated contours of vorticity (1/s) under stoichiometric condition with varying: (a) hydrogen fractions at $U_{in}=5.2$ m/s, (b) oxygen fractions at $U_{in}=5.2$ m/s, and (c) bulk throat velocities at $HF=20\%$ and $OF=30\%$

4.2.2 Combustion and Emission Attributes of $CH_4/H_2/O_2/CO_2$ flames

Hydrogen-enriched premixed flames characteristics are analyzed by investigating the product formation rate (*PFR*). Figure 3.18 shows the effect of *HF*, *OF*, and bulk throat velocity U_{in} on the product formation rate (*PFR*) – an important combustion parameter. With hydrogen (Figure 3.18a) and/or oxygen (Figure 3.18b) addition, the *PFR* in relatively thin inner shear layer increases, resulting in compact flames. The influence of the *OF* on *PFR*, however, is comparatively greater than that of *HF*. At lower bulk throat velocity, on the other hand, *PFR* in the inner shear layer increases resulting in shorter flame structure (Figure 3.18c). The effect of inlet velocity on *PFR*, however, is small which implies that chemical aspects of the flame dominate compared to its physical features in terms of the rate of product formation. The numerical model does not capture the stability transition of

the flames from the ORZ to the IRZ, but the trend of *PFR* sheds light on it. Flame images from Figure 3.14 can be recalled for corner flame stabilization at lower *HF* and *OF*, and high U_{in} indicating the dominant role of the *ORZ* on flame stability; however, its role diminishes with increasing *HF* and *OF*, and lowering U_{in} .

Figure 3.18 - Calculated contours of product formation rate (1/s) under stoichiometric condition with varying: (a) hydrogen fractions at $U_{in}=5.2$ m/s, (b) oxygen fractions at $U_{in}=5.2$ m/s, and (c) bulk throat velocities at $HF=20\%$ and $OF=30\%$

Another important parameter is reaction progress variable c for characterizing flame structure, and for indicating the degree of completion of the combustion reaction by showing conversion from unburnt reactants to entirely burnt products (complete combustion). The contours of progress variable in Figure 3.19 represent the influence of *HF*, *OF*, and throat velocity on the progress of the reaction. The individual impact of increased oxygen- and hydrogen-enrichment on the progress variable do not seem to be significant as the figure hardly show any differences particularly in the near-exit location

of the burner where the flame stabilizes. Similarly, the increase in bulk throat velocity also does not make any difference to the flame thickness (represented by progress variable) even though the resulting increase in angular momentum dislocate the flame-front by pushing it outwards. It is also worthy to note here that the resulting increase in turbulence hardly affect the flame thickness, suggesting the dominant role of chemical kinetics which remains unaffected by the flow dynamics.

For analyzing the emissions characteristics of the flames under investigation, mole fraction distributions of CO, OH, CO₂ and H₂O species are studied (Figure 3.20). The results of hydrogen-enrichment are witnessed with increased CO and reduced CO₂ concentrations. One of the possible reasons is the increment in *HF* makes more H species available, which compete with CO for its reaction with atomic O; thereby retarding CO₂ and increasing OH formation. Atomic O and H tend to react at first hand, as compared to the CO oxidation to CO₂. In addition, increasing *HF* results in increased combustor temperatures for the premixed stoichiometric oxy-methane flames, which consequently becomes a reason for the CO₂ dissociation into CO and O species. This phenomenon would have dominated and resulted in the increased CO concentrations. Furthermore, the availability of more H species due to hydrogen-enrichment, increases the formation of H₂O through OH.

Figure 3.19 - Calculated contours of progress variable under stoichiometric condition with varying: (a) hydrogen fractions at $U_{in}=5.2$ m/s, (b) oxygen fractions at $U_{in}=5.2$ m/s, and (c) bulk throat velocities at $HF=20\%$ and $OF=30\%$

The mole fraction of CO and OH species increases with rising OF . The availability of increased concentrations of O_2 makes the possible break down of CH_4 and H_2 molecules and oxidation results in CO and OH species. CO_2 is one of the complete combustion products but also, it is part of the reactant oxidizer mixture. On one side, CO is oxidizing to CO_2 but because of the elevated temperatures, the breaking effect of CO_2 into CO and O species prevails and therefore increasing OF would have resulted in increased CO while reduced CO_2 concentrations. In addition, increasing the OF enhances OH oxidation and therefore results in increased concentrations of H_2O .

Figure 3.20 - Calculated dimensionless mole fractions of CO, OH, CO₂, and H₂O distributions under stoichiometric condition with varying hydrogen and oxygen fractions

Figure 3.21 shows the behavior of hydrogen fraction, oxygen fraction, and inlet velocity affecting the total thickness of the flame ($\delta = \text{preheat zone} + \text{reaction zone}$) ($\delta = \pi(\delta)$). Augmenting the concentrations of hydrogen and oxygen gases further make the flame thinner as indicated in Figure 3.21a and Figure 3.21b, respectively. It is worthy to mention that reduction of flame thickness is more severe with increasing OF as compared to HF . Bulk throat velocity is the physical property of the mixture and, therefore, it puts negligible effect on flame thickness. Figure 3.22 represents the changes in Damköhler number (Da) with HF , OF , and U_{in} . The Da significantly enhances with the increments in hydrogen and

oxygen, witnessed in Figure 3.22a and Figure 3.22b, indicating faster reaction with more addition of each gas. Moreover, the increase of the inlet velocity results in reduction of the Da (Figure 3.22c), because transport time scale overwhelms chemical time scale relatively as a consequence of reduced residence time. Furthermore, value of Da is more than unity for all investigated cases, representing influential role of chemical kinetics on flame characteristics. The flame structure is thin and increased value of Da indicates the prominent part of laminar burning rate, while turbulence does not alter the inner structure of the flame because of thinner flames and disturbs the overall outer structure of the flame. That seems to be the reason behind wrinkled and spread-out flames.

Figure 3.21 - Effects of: (a) hydrogen fraction and (b) oxygen fraction (both at $U_{in}=5.2$ m/s and $OF=30\%$) on calculated flame thickness under stoichiometric condition

Figure 3.22 - Variation of calculated Damköhler number (Da) under stoichiometric condition as function of: (a) hydrogen fraction at $OF=30\%$ and $U_{in}=5.2$ m/s, (b) oxygen fraction at $OF=30\%$ and $U_{in}=5.2$ m/s, and (c) bulk throat velocity at $HF=20\%$ and $OF=30\%$

CHAPTER 5

CONCLUSIONS

The stability and combustion characteristics of oxy-propane ones ($C_3H_8/O_2/CO_2$) and oxygen-enriched air-propane flames ($C_3H_8/O_2/N_2$) were analysed and compared using a model gas turbine combustor, under identical conditions of oxygen fraction ($OF = 21\% - 70\%$) and equivalence ratio ($\varphi = 0.1 - 1.0$). Operational air-fuel gas turbine combustor's geometry was mimicked by the investigated swirl-stabilized combustor implementing LPM DLE technology. Throughout the study, the flow rates of the non-preheated reactant gases were adjusted for establishing a common inlet velocity of 5.2 m/s and for maintaining similar turbulence intensities and flow conditions. The enrichment of atmospheric air with pure oxygen was used for the production of artificial air (O_2/N_2) of specific OF . The stability map of the combustor was plotted based on quantification of the blowout and flashback flame extinction limits within φ - OF domain. Adiabatic flame temperature (AFT) was mapped over the same test ranges for both CO_2 and N_2 flames. In addition, the behavior of constant AFT was investigated in detail, over the flames' macrostructure and stabilization by imaging selected flames. For the common bulk throat velocity of N_2 and CO_2 flames, the subsequent novel conclusions were identified. (a) The constant AFT contours were distinct of individual flames, yet their stabilization zones can be clearly characterized by AFT alone. Thus, under similar flow conditions, the reaction kinetics primarily govern the stable combustion zones. (b) While increasing the AFT of both CO_2 and N_2 flames from blowout to flashback limit, similar changes occur in the macrostructure

and stabilization mode. (c) Flames with similar AFT possess similar flame shape, even though the OF and φ are different, which proves the dominance of reaction kinetics in the behavior of flames. It also demonstrates that the information of AFT alone is useful enough to accurately predict the macrostructure and stability of CO_2 and N_2 flames with constant bulk throat velocity. Axial and radial temperatures were measured inside the quartz confinement for investigating the field of flow. Based on the prevailed findings, this thesis work proposes the design and operation of prospective oxy-propane gas turbines founded on AFT (and not on φ or OF).

Moreover, Stoichiometric premixed $CH_4/H_2/O_2/CO_2$ flames are numerically simulated incorporating Large Eddy Simulations (LES) for investigating effects of hydrogen-enrichment (HF), oxygen fraction (OF), and bulk throat velocity (U_{in}) on flame characteristics and stability, as well as the resulting emissions. Three constant velocities were investigated in this analysis i.e. 4.4 m/s, 5.2 m/s and 6.0 m/s. The outer recirculation zone (ORZ) plays a significant part in flame stabilization at lower values of HF and OF , but its role diminishes at higher values. The inner recirculation zone (IRZ) is mainly characterized with the formation of secondary eddies whose number and size strongly depends upon the HF and OF of the mixture.

The rate of reaction increases significantly with increasing HF and OF , because of the increased concentrations of chemically active radicals. The concentration of CO enhances whereas the mole fraction of CO_2 reduces with increasing HF . Elevated temperatures trigger the CO_2 dissociation into CO and O atoms. In addition, increased OH species are noticed because of the availability of more H species. CO_2 also reduces down with increasing CO emissions at higher OF . The accessibility of more O atoms to CO would

cause improved oxidation to CO_2 however, the dissociation of CO_2 because of higher temperatures, prevails its formation. With increasing HF and OF , the Damköhler number (Da) boosts and reduces down with increments in the bulk throat velocity. The higher values of Da suggest that, although the swirl-generated turbulence slightly affects the macrostructure of the flame, the flame's compositional structure is governed by the overall stoichiometry such that the propagation reactions dominate the flame-front region and keep its micro-structure largely intact.

CHAPTER 6

FUTURE WORK

- The premixed $C_3H_8/O_2/N_2$ and $C_3H_8/O_2/CO_2$ flames can be numerically studied for further insight on the attributes of efficient combustion and reduced emission operations.
- This combustor can be used for conducting experiments with biogas and comparative studies can be made with available literature on premixed combustion of fossil fuels.
- The hydrogen-enrichment effects on premixed $C_3H_8/O_2/N_2$ and $C_3H_8/O_2/CO_2$ flames can be studied.
- Micromixer stabilized $C_3H_8/O_2/CO_2$ and $C_3H_8/O_2/N_2$ flames can be studied and compared with swirl stabilized ones.
