## ACKNOWLEDGEMENT

Acknowledgement and praise is first due to Almighty Allah for allowing me to complete this work.

Acknowledgement is also due to King Fahd University of Petroleum & Minerals and to the Schlumberger, Dhahran Carbonate Research Center for their support in carrying out this research.

Before mentioning anyone else, the author would like to express his profound gratitude to his thesis advisor Dr. Abdulaziz U. Al-Kaabi for his guidance, suggestions, excellent ideas, valuable time, and for his continuous support. The author expresses his appreciation to him as his guardian during his studies at this university. The author feels deep pleasure to have such a wonderful and disciplined person as his guide and guardian.

The author has no hesitation to say that he was very lucky to have a chance to work with an experienced and friendly person like Dr. Kamal Babour (Director of Dhahran Carbonate Research Center, Schlumberger) for more than a year. The author appreciates the experience and support he received from Dr. Babour and is very much grateful to him, as he promoted and encouraged the idea of this research.

The author wishes to extend his appreciation to Dr. Erle C. Donaldson for his valuable support and special care for this research. He was always very helpful to the author with suggestions and comments from a distant place (the U.S.A.), which were needed at each

step of the work. The author is also grateful to Mr. Philippe Souhaité for his great cooperation and help during his visits from France.

The author is grateful to Dr. Hasan Al-Yousef (member of the thesis committee) for his excellent ideas and contributions drawn from his wealth of experience. Similarly, the author wishes to extend his appreciation to the other thesis committee members, Dr. Khalid Al-Fossail (Chairman, Petroleum Engineering Department) and Dr. Habib Menouar, for their cooperation and help. Special appreciation is due to the former Chairman of the Petroleum Engineering Department, Dr. Abdulaziz Al-Majed, for his continuous encouragement and support.

The author is grateful to all the staff of the Petroleum Engineering Department for their special care and help throughout the experiment and also deeply grateful to Mr. C. Selander of the Research Workshop for his help in constructing the reservoir model.

The author wishes to express his appreciation to Dr. A. Mohiuddin, Mr. Bechir Mtawaa, Mr. Kissami Mimoune, Mr. Rajan, Mr. Ajaz A. Khan, Mr. E. Bize, Mr. Munir Al-Fattah, and Mr. Asif Sultan for their encouragement and help during the course of this work.

Acknowledgement is also due to the author's fellow graduate students and to the members of the Bangladeshi community for their encouragement and support. The author is of course, grateful to his parents, brothers, and other family members for their patience and encouragement throughout his life.

## **ABSTRACT**

FULL NAME: MUHAMMAD REAZ UDDIN CHOWDHURY  
TITLE OF STUDY: MONITORING FLUID FRONT MOVEMENT USING  
PERMANENT RESISTIVITY ARRAYS  
MAJOR FIELD: PETROLEUM ENGINEERING  
DATE OF DEGREE: MARCH 2003

Knowledge of fluid movement in the reservoir is a key to reducing production cost and to increasing ultimate recovery. The main objective of reservoir fluid monitoring is to provide a reliable temporal description of the fluid front propagation resulting from fluid injection and production.

This study represents the first experimental work to study the feasibility of fluid front monitoring using Permanent Resistivity Arrays in a well centered in a circular drainage area. A visual sector model that represents  $1/16^{\text{th}}$  of the circular drainage area was designed and constructed. The production/injection well was equipped with permanent resistivity arrays. Advanced data acquisition system was used to inject current and to measure electric potential.

The experimental data were then simulated numerically using a finite element numerical model developed by Schlumberger. A good match was obtained between laboratory and numerical results. The model was also used to understand the influence of various parameters on the measurements.

The results of this study indicate that resistivity measurements are very sensitive to fluid movement and that Permanent Resistivity Arrays can easily be used to monitor fluid front movement. It was demonstrated through this work that fluid front can be detectable up to a distance equaling twice the length of the resistivity array and the detection level could even be improved several fold if the sensitivity of the measurements are improved. The resistivity measurements were also found to be sensitive to the orientation of the fluid front.

## ملخص

الإسم : محمد رياض الدين شودري

عنوان الرسالة : مراقبة حركة مقدمة الموانع باستخدام صفوف دائمة للمقاومية .

التخصص : هندسة البترول

تاريخ التخرج : مارس 2003م.

إن معرفة حركة الموانع في المكن من أهم العوامل الرئيسية في تخفيض تكلفة الإنتاج، وزيادة الانتاجية الكلية. وإن الهدف الرئيسي لمراقبة حركة الموانع في المكن هو تقديم وصف مرحلي موثق لانسباب الموانع الناتجة من عمليات الغمر والإنتاج .

وتمثل هذه الدراسة أول عمل تجريبي لدراسة جدوى مراقبة حركة الموانع باستخدام صف دائم للمقاومية في بئر يتوسط حقل دائري. ولقد تم تصميم وإنشاء نموذج شفاف لمقطع دائري تمثل جزءاً واحداً من ستة عشرة جزءاً من الحقل الدائري ، مع تزويد بئر الإنتاج والغمر بصف دائم من أقطاب كهربائية لقياس المقاومة واستخدام نظام متطور لضخ تيار كهربائي وقياس الجهد الناتج.

وتم محاكاة البيانات المتحصلة من التجارب حسابياً باستخدام نموذج حسابي مطور من قبل شركة شلمبرجيه . و تم الحصول على نتائج متطابقة مع تلك المتحصلة من التجارب . كما تم استخدام المحاكى في دراسة تأثير العوامل المختلفة على القياسات .

ولقد أظهرت نتائج الدراسة على أن المقاومة حساسة جداً لحركة انسياب الموانع في المكن وأن نظام الصفوف الدائمة للاقطاب الكهربائية لقياس المقاومة يمكن استخدامها بكل يسر في تحديد حركة مقدمة الموانع على مسافة تعادل ضعف طول صف المقاومة في البئر، ويمكن زيادة ذلك عدة مرات باستخدام أجهزة قياس أكثر حساسية . وكما أظهرت النتائج أن قياس المقاومة تتأثر بدرجة ميلان المقدمة.

## **INTRODUCTION**

## **CHAPTER 1**

### **INTRODUCTION**

Tracking the movement of reservoir fluids during production has great importance in reservoir management and in improving recovery since it provides advance warning of changes in production behavior. This warning may help to prolong the life of the well. Knowledge of fluid movement in the reservoir is a key to reduce production cost and to increase ultimate recovery.

Currently most of the vital data about the reservoir are obtained under the form of production or pressure behavior. Water breakthrough at a well, however, usually signals a decline in the well's desired production rate. Reliable advance knowledge of the locations of fluid interfaces allows remedial actions to be taken to extend the life of the well.

Geophysical techniques have been used for reservoir delineation and description for several decades. Recently, attempts have been made to adapt geophysical techniques to actively monitor secondary and tertiary recovery processes such as water, and steam flooding. It has been realized that the detection of changes in geophysical response over time can be used to estimate the lateral extent and volume of the reservoir affected by the enhanced recovery processes. The main objective of monitoring is to provide a reliable

temporal description of the fluid front propagation resulting from fluid injection and production. These data are usually supplemented with production data and observation well histories and used to estimate reservoir recovery efficiency and to plan continuation of production cycles. In fact, such data help to optimize the design and to improve control of the well because they provide an independent measurement of the recovery behavior.

The most interesting approach in geophysics for reservoir monitoring is associated with repeating geophysical surveys with great precision at different times during reservoir depletion. This allows the use of time differential data (changes over time) rather than evaluating the reservoir based on a single survey (one time absolute measurement and interpretation). For reservoir monitoring, time-lapse measurements are obviously vital. Besides, time-lapse measurements can be interpreted directly in terms of reservoir parameter changes, rather than by doing absolute interpretations and then comparing them to study the changes in the reservoir parameters.

Electrical methods are more sensitive to fluid content than seismic methods, which are essentially sensitive to the rock matrix properties (except in the case of gas reservoirs). Because of this sensitivity to fluid content, electrical techniques can be used to complement seismic methods in reservoir monitoring. The recent advancements have in borehole electric and electromagnetic transmitters and receivers for cross-hole and subsurface-to-surface electrical surveys opened the possibilities of reservoir monitoring over time for reservoir management.

At present, permanent monitoring systems are increasingly used to measure and record well performance and reservoir behavior from sensors placed downhole during completion. Modern communications provide remote access to measurements of reservoir parameters. Engineers can watch performance continuously, examine responses to changes in production or secondary recovery processes and also have a record of events to help diagnose problems and monitor remedial actions. Most systems in operation record bottom-hole pressure and temperature, but other measurements, such as flow rate, are increasingly becoming common. When pressure and rate are measured within the wellbore, fluid saturation is evaluated around or at some distance away from the wellbore. In the same way that electrical logging resolves the distribution of fluid saturation around the wellbore, permanent-monitoring tools aim at delivering a more complete answer with a greater depth of investigation.

The aim of this research is to study the application of Permanent Arrays of Electrodes as a method for monitoring fluid front movement in a scaled reservoir model. The study will answer the following questions:

- ☛ Can we use electrical method to detect fluid front movement?
- ☛ If yes,
  - How far can we detect the front?
  - How sensitive is the measurement?
  - What is the effect of controlling factors?
  - Can we numerically simulate the results?
  - What is the effect of front orientation?

## *Chapter 2*

### ***LITERATURE REVIEW***

## CHAPTER 2

### LITERATURE REVIEW

The desire to prevent early water production has created a growing demand for accurate tracking and imaging of fluid front movement in hydrocarbon reservoirs. Various methods were tried to provide an image of fluid movement in the reservoirs. Currently, permanent monitoring methods including permanent electrode arrays are being evaluated in various locations including local Saudi Formations. Following is a summary of work done related to fluid movement monitoring in hydrocarbon reservoirs.

**Dunlop, King, and Breitenbach (1991)**<sup>(1)</sup> described a monitoring technique that used repeated seismic surveys to detect saturation changes at locations distant from wells. The monitoring technique integrates the data currently used for prediction of reservoir behavior with measurements made by repeated surface-seismic-reflection surveys. The continuity of seismic information along cross-sections is integrated with the 3-D coverage provided by simulation. This creates a field model in which the fluid location can be verified by direct measurement. Repeated surveys and simulations provide feedback that refines the accuracy of the field model.

**Khalaf (1991)<sup>(2)</sup>** used responses from pressure buildup surveys to distinguish between gas and waterfronts and to determine the distance to either of these fronts long before the fronts reach the wellbore in the Umm Sharif field. The gas front behaved as a constant pressure boundary, while water acted as a pressure-support boundary. The field was producing for a long time and the fluid fronts moved significantly from their original locations. The tracking of fluid movement was achieved through TDT logging and monitoring gas and water production.

**Mills (1993)<sup>(3)</sup>** used Time-Lapse interpretation effectively in low-salinity formation for quantitative interpretation although formation responses often are masked by larger responses caused by changes in the logging environment. In his work, several techniques, such as using the Gamma ray log to indicate formation water movement, are used to aid interpretation because accurate quantitative interpretation of Pulsed-Neutron-Capture (PNC) logs cannot be achieved in the low salinity formation water environment of the Gippsland basin. This is because formation fluid movement responses are small relative to uncertainties introduced by lithologic variation.

**Erga, and Knuston (1991)<sup>(4)</sup>** described the fluid distribution in the Beryl formation, which has a complicated distribution of pressures and fluids. Horizontal permeability restrictions, the result of extensive faulting, subdivided the reservoir into eight inter-related areas as determined by careful analyses of pressure histories, production histories and fluid monitoring. They described the methodology for constructing a conceptual reservoir model for the Beryl reservoir to identify areas of upswept hydrocarbons,

resulting in an aggressive drilling program, and optimize the effort in simulation history matching.

**Narayan and Dusseault (1995)<sup>(5)</sup>** showed that three-dimensional electrical resistivity tomography might be used to track propagation of fluid fronts over time. They present general requirements for resistivity tomography in EOR, typical electrode installations to reduce noise and seasonal variations, requirements for a general inversion of a 3-D resistivity problem in EOR, sensitivity analyses for a shallow reservoir case subjected to EOR, and a method of rapid design and evaluation of resistivity monitoring. The analytical tools and technology are now adequate to re-evaluate and develop electrical monitoring for EOR applications.

**Brady, Wolcott, and Ferguson (1995)<sup>(6)</sup>** developed and tested a unique method to monitor water movement in a gas cap reservoir in an Arctic environment. The novel surveillance technique for monitoring the water movement had to be developed given the very limited number of wells that penetrate the gas cap, whereas conventional fluid monitoring techniques require drilling numerous observation wells to adequately monitor water movement. Modeling studies indicate that the density changes associated with water replacing gas can be detected using high-resolution surface gravity measurements. Modeling gravity effects of water movement for mass distribution, mass balance and water front detection were also discussed. A test of the gravity meter and essential high-precision station positioning under typical Arctic winter conditions were evaluated using the Global Positioning System (GPS).

**Unneland and Haugland (1994)<sup>(7)</sup>** presented experience with and applications of permanent downhole pressure and temperature gauges in the reservoir management of two complex North Sea oil fields, Gullfaks and Veslefrikk. In total, 40 quartz and capacitance gauges had been installed in platform wells for 6 years. The gauges provide invaluable real time data for reservoir management of these two fields and contributed directly to increased daily oil production. The installations proved to be safe and reliable, as well as good investments. The decision to install permanent gauges was based on three primary factors:

1. The need for enhanced reservoir description, especially during the initial production time.
2. Increased production resulting from a combination of less downtime for data acquisition and optimization of reservoir and well management.
3. Safety and operational considerations.

Large investments before production startup are typical for most North Sea developments, requiring a high early production to ensure project profitability. At the same time, reservoir complexity and relatively short field lifetimes necessitate extensive data acquisition during the initial production phase. Permanent gauges supported both requirements by supplying continuous downhole data with a minimum well downtime.

**Phillip, Roy, and Walter (1982)<sup>(8)</sup>** used Pulsed Neutron Capture (PNC) Logs to determine residual oil saturation. Previous study showed that, at low values of residual oil saturation (ROS), conventional PNC logging techniques did not have the accuracy necessary for enhanced oil recovery decision-making requirements. So they developed and used special log-inject-log techniques in order to reduce the uncertainty in the values of ROS measured with PNC logs. A study of the uncertainty associated with ROS values determined with PNC logs was made using Monte Carlo simulation techniques. Field data was obtained from tests reported in the literature. Using a more realistic confidence interval of 95%, the expected accuracy of the ROS values was found to decrease by at least a factor of two in tested wells.

**Donaldson, Madjidi, and White (1991)<sup>(9)</sup>** presented an experimental work to show that the concept of the focused current logging tool could be extended to cross-well potential measurements to determine the inter-well fluid saturation distribution. A model reservoir, 8 feet in diameter with 20 inches of sand between two layers of shale, was saturated with 80000 ppm of sodium chloride. Eleven wells were located throughout the reservoir and a scaled nine-electrode laterolog was used to provide the focused current. Electrical potentials measured at each well were used to map the isopotential lines. The uniform sodium solution was then changed at one well by injecting fresh water and isopotential maps of the saturation abnormality were made. Dissipation of the saturation abnormality with respect to time, due to counter-current diffusion, was also tracked.

A Finite Element Mathematical Model using Poisson's and Archie's equations was prepared. The exact dimensions of the model reservoir and the experimental input data were used in the computer program. Using these data, the computer program produced maps of isopotential lines. The results indicate that this could be developed into a technique to measure the inter-well saturation distribution in reservoirs. It also could be used for the location of saturation anomalies and discontinuities, caused by geological structure changes, between wells.

**Augustin, Kennedy, Morison, and Lee (1988)<sup>(10)</sup>** explained a new logging method, in which the source is a horizontal loop, coaxial with a cased drill hole and the secondary axial fields are measured at depth within the casing. If the casing response cannot be accurately predicted, a separate logging tool employing a higher-frequency transmitter could be used to determine the required casing parameters in the vicinity of the reservoir. The logging technique showed excellent sensitivity to changes in formation conductivity. One of its most promising applications is in monitoring, through repeated measurements, changes in formation conductivity during production or enhanced recovery operations.

**Xu and Noel (1993)<sup>(11)</sup>** described how potential data can be obtained for use in electrical resistivity imaging, using a surface linear array of equally spaced electrodes. The aim was to collect a complete data set, which contains all linearly independent measurements of apparent resistivity, with such an array using two-, three- or four-electrode configurations. From this primary data set, it was shown that any other value of apparent resistivity on the array could be synthesized through a process of superposition.

Numerical tests showed that such transformations were exact within the machine error for calculated data but that their use with real field data may lead to noise amplification.

**Poirmeur, and Vasseur (1988)<sup>(12)</sup>** showed that hole-to-hole electrical measurements could be used to localize and define the extension of conductive bodies whether or not they were penetrated by the holes. Two promising applications of this electrical method are the optimization of mining boreholes and delineation of fractures. A program was developed to compute the electrical potential caused by direct current injection in an inhomogeneous half-space.

**Gorden, Lovell, Miriari and Tezuka (1990)<sup>(13)</sup>** modeled arrays of pole-pole and dipole-dipole electrical logs of ultra long spacing in an environment with a conductive borehole and resistive formation. The forward modeling had been done with 2-D and 3-D finite element codes solving Laplace's equation. Logs of the same electrode configuration had been run in a well drilled in a hot dry rock geothermal reservoir and the same modeling capability had been used to attempt inversion of those logs. The logs showed indications of local mechanical and thermal stress related to micro fractures as well as long but sparse natural fractures intersecting the borehole. The micro fractures were modeled as zones of finite conductivity and the location and conductivity values of those zones were estimated by 2-D iterative modeling.

**Imamura (1992)<sup>(14)</sup>** attempted to image the near borehole resistivity structure using the apparent resistivity from normal resistivity logs. An axis metric FEM and 4CST

elements were used to calculate the theoretical apparent resistivity. The apparent resistivity of the FEM result showed good agreement with an analytical solution and a resistor network solution. Using the technique, it is possible to elucidate a variation of resistivity in radial direction. The technique can potentially be applied to estimate formation permeability, by comparing the image obtained at different times.

**Mansure, Meldau, and Weyland (1993)<sup>(15)</sup>** showed how the relationship between the process and formation resistivity, which is an essential part of electrical geo-diagnostic techniques to map thermal recovery processes, is used to interpret electrical well logs and can be used to understand steam flood resistivity changes. Examples are presented of data from steam floods in fields with different reservoir characteristics. Included is a typical heavy-oil steam flood and a steam flood where fresh water is used for the steam generator feed water. Because of differences in reservoir characteristics, changes in resistivity vary from reservoir to reservoir. The information presented includes well logs taken before and after steam flooding and petrophysical measurements sufficient to determine the factors that controlled the resistivity changes in the field.

**Kleef and Babour (2001)<sup>(16)</sup>** reported a project launched by Schlumberger and Shell to prove the concept and economic viability of Dynamic Reservoir Drainage Imaging (DRDI). The goal was to provide a time-lapse monitoring of water saturation, allowing evaluation of drainage efficiency in oil and gas reservoirs. To achieve this objective, the resistivity approach was used. In this technique, an array of electrodes is cemented at reservoir level, providing a continuous reading of the formation resistivity. Applications

of this technology include real-time monitoring of water cone development and water table rise, provided there is a sufficiently large resistivity contrast between hydrocarbon and water zones.

In the case of a water flood, as the water front approaches the array the current lines are distorted, resulting in a variation in electrical potentials when compared with the base case with no water. Downhole resistivity was selected for its ability to monitor fluid-front advancement and detect approaching water. Seismic sensors were originally considered as complementary sensors at the beginning of the project. The well completion design was optimized in order to ensure a safe deployment of the electrical array cable and well integrity. On the application side, the data acquired by Dynamic Reservoir Drainage Imaging (DRDI) so far have cast a new light on the dynamic processes taking place in the reservoir. The interpretation of the time lapse DRDI data has shown that the water sweep was vertically uneven and that early water breakthrough was to be expected at the producer wells. Production data and saturation logging confirmed the above interpretation.

**Bryant, I.D. et al. (2002)<sup>(20)</sup>** explained the application of electrical measurement technologies to permanent reservoir monitoring. The principle objective of the experiment was to demonstrate the feasibility of monitoring water movement between an injection and an observation well. They were able to generate and present good signal-to-noise ratio and high reciprocity. They demonstrated the viability of using permanently installed resistivity arrays to monitor the movement of oil/water contacts and salinity

fronts that are some tens of feet away from the wellbore. Results demonstrated the feasibility of using such arrays to monitor the movement of oil/water contact from injection, monitoring and production wells.

**Charara, M et al. (2002)** <sup>(21)</sup> deployed permanent downhole electrodes successfully in oil wells to track oil fields under secondary recovery such as water flooding, where an even reservoir sweep or zones of bypassed oil could be defined by the proper description of the waterfront advance. They have described the use of pressure buildup from repeated shuts in association with the electrical measurements. They have published a quick look method for interpreting the time-lapse pressure transients with a comparison of the physical and practical advantages of each type of measurement and the domain of application of the two measurements with respect to fluid and reservoir properties.

### **STATEMENT OF THE PROBLEM AND STUDY OBJECTIVE**

#### **3.1 STATEMENT OF THE PROBLEM**

Reservoir development and management traditionally rely on early data gathered during short periods of logging and testing before wells are placed on production. Additional data are generally required after a long period of production, either as a planned exercise or when unforeseen problems arise. Such data acquisition requires well intervention and always means loss of production, increased risk, inconvenience and logistical problems, and may also involve the additional expense and time of bringing a rig to the location.

Permanent monitoring systems are helpful to avoid the above stated problems. Those systems measure and record well performance and reservoir behavior from sensors placed downhole during completion. Such measurements give engineers information essential to dynamically manage hydrocarbon assets, allowing them to optimize production, diagnose problems, refine field development and adjust reservoir models.

According to the previous literature survey presented in Chapter 2, there has been increasing interest in using permanent downhole arrays to track the movement of the planar front in the reservoir. The following observations were made from the literature survey:

- a. There is no previous laboratory work to study permanent downhole arrays of electrodes for tracking of fluid front movement in reservoirs.
- b. The idea of using permanent resistivity arrays is relatively new with limited field experience. Further understanding of the factors influencing the measurements is very much needed.
- c. There is limited published work on interpreting multiple well data with the use of permanent resistivity arrays.
- d. In all the reported studies, the front is assumed as a moving plane. No previous study looked at a front moving toward the well in a radial direction.
- e. There is a need to optimize the utilization of wells equipped with permanent resistivity arrays.

Our study was aimed at further advancing knowledge in utilizing permanent resistivity electrodes and the use of electrical methods in tracking fluid movement in reservoirs. A scaled physical model and a numerical simulator were used to study fluid front movement over time in cylindrical coordinate using permanent arrays of electrodes in a single well arrangement with a single source of current.

### **3.2 OBJECTIVES OF THIS STUDY**

The objectives of this study were to:

- a. Implement permanent downhole arrays of electrodes in a scaled reservoir model that represents a cylindrical drainage area.
- b. Vary the current injection rate, electric potential and spacing of electrodes to get different measurement conditions.
- c. Use the setup to measure the change in resistivity due to change in fluid content and distribution.
- d. Validate and utilize a numerical model in the analysis of acquired resistance or potential data.

### **3.3 PROPOSED APPROACH**

In order to accomplish the above objectives, the following approach was proposed:

- a. Design and construct a scaled reservoir model.
- b. Design and implement model wells equipped with permanent arrays of electrodes.
- c. Measure the potentials between the array electrodes and a reference electrode located at a distant place.

- d. Interpret the experimental data to determine the movement of the fluid front.
- e. Validate and utilize a Mathematical Model (developed by Schlumberger) to analyze experimental data.

### 3.4 STUDY PLAN

The following plan was used to achieve the above objectives:

1. Implement permanent resistivity arrays in an injection / producing well to study the behavior of the resistances with the movement of fluid. From the electrical viewpoint, if there is a large resistivity contrast between the zones mostly saturated with oil and water, the measured resistance should change significantly if the fluid in any zone is changed from oil to water or vice versa. By observing the change in measured resistances, it might be possible to get an indication of the position of the oil water interface.
2. Fabricate a model made of one-inch thick plexiglas sheet to represent a sector in a cylindrical drainage area where a producer well is surrounded by water in all directions.
3. Use a Teflon tube with several electrodes mounted on its surface to represent the well with the permanent resistivity arrays.

4. Eliminate the gravity effect on the orientation of the front by conducting experiments while the model is positioned vertically.
5. Use a state-of-the-art data acquisition system (from Schlumberger) to measure the resistances along the electrodes with respect to the reference electrode.
6. Validate a mathematical model and then use it to analyze the collected data to define the position of the fluid front in the reservoir.

***PROCEDURE***

## **CHAPTER 4**

### **EXPERIMENTAL APPARATUS AND PROCEDURE**

#### **4.1 EXPERIMENTAL SETUP**

Based on the objectives of this study, there was a need to fabricate two models (one to represent the reservoir and another to determine fluid properties). Their design and implementation were done with the help of the personnel from the Petroleum Engineering Department and the Research Workshop. Below is a description of the two models.

##### **4.1.1 SECTOR MODEL**

A transparent 3-dimensional scaled model, made out of plexiglas (one inch thick) was used for the main part of the study. 30-40 mesh glass beads were used to represent the porous media of the reservoir. The model has a wedge shape and represents  $1/16^{\text{th}}$  of a polygonal-shaped reservoir. The polygonal shape approximates a cylindrical reservoir with fluid flow in a radial direction (Figure 4.1.1). The length of the two equilateral sides of the sector model is 100 cm each and the base is 40 cm long. The height of the reservoir model is 30 cm when it is in the horizontal position.

**Figure 4.1.1: Top View of (a) Cylindrical Model, (b) Using Sector Model as 1/16<sup>th</sup> of Polygonal Shape.**

All the sides of the plexiglas model were fixed to each other with epoxy glue and long screws to make it completely sealed except for the top cover. The extended portions of the top plate were connected to the extended portions of the bottom plate (shown later in Figure 4.2.3) with screws and nuts keeping the rubber liner in the joint of the top and the side plates only to make it sealed and removable if needed.

Fluids were injected into the sector model using wells. A 30 cm long transparent Teflon tube of 0.6 cm ID was used to simulate the main well (used as production well for most cases) centered in a circular reservoir. The main well was perforated and a filter was mounted in front of the other well. The 30 cm well had 30 perforations per cm. The diameter of the perforations was selected to be 0.4 mm to keep glass beads from getting through during production.

Thirty-one electrodes were mounted on the main well and were connected to the acquisition system to measure electric potential. Two more electrodes were inserted in the base plate of the model; they were used as reference electrodes. Eight electrodes were inserted along the top plate to measure the change of resistivities of the porous media. The top electrode mounted on the well and one of the reference electrodes were used for current injection while the other electrodes on the well and the other reference electrode were used to measure potentials. To improve measurement accuracy and to alleviate difficulties discussed later, extra eighteen electrodes were positioned a few centimeters below the injection well and inserted directly into the porous media from the sides (Figure 4.12 and Figure 4.13).

**Figure 4.1.2: Schematic of (a) Sector Model, (b) Measurements with the Model Keeping at Vertical Position.**

**Figure 4.1.3: A Side View of Sector Model.**

#### **4.1.2 ONE DIMENSIONAL CYLINDRICAL MODEL**

Another physical model, made of Plexiglas, was used for the following reasons:

1. To establish experimental procedures and measurement conditions before attempting measurements on the sector model,
2. To become familiar with resistivity behavior under different water salinity and oil combinations, and
3. To study the maximum allowable resistivity for the fluid pair used to saturate the model with.

This one-D model was cylindrical in shape and fabricated with a plexiglas tube having an inner diameter of 3.98 cm and a length of 37.8 cm. The two ends of the cylinder were closed with Plexiglas plates and two sealed tubes were inserted into those plates with metallic connectors to allow fluid flow through the model. Eleven electrodes were inserted in the cylinder along its length and two others were connected at each end to inject current. The electrodes were equally spaced (3 cm) along the model and the geometric factor of the cylindrical model is exactly determined. Numerous measurements were conducted using the cylindrical model to understand the change in resistivity and the experimental procedures.

The cylinder was packed in the same way as the sector model. Figure 4.1.4 is a schematic of the cylindrical model and the experimental setup.

**Figure 4.1.4: (a) Cylindrical Model with electrodes (b) Schematic of the Cylindrical Model with Set-up.**

#### **4.1.3 ACQUISITION SYSTEM (ERAS)**

The acquisition system is a general-purpose current injection and data acquisition system allowing the following:

- Injection of current between 2 electrodes (Max 2 A, 300V),
- Measurement of potentials, and
- Operation in a frequency band from 0.01 to 500 Hz

The system is controlled by a PC and can perform sequences of current injection and measurement between any combinations of electrodes.

The system was connected to a 110-volt line. Injection of current during the study was limited to 20 mA and the maximum voltage used was 300 V. All measurements were done at 10 Hz. At this frequency, the equation of DC approximation is valid and polarization effects of electrodes are avoided. The shapes of measured potential and injected current are displayed together with the corresponding values during measurement sequences. This feature allows the detection of any error during measurement. The system was originally designed for actual field measurements. Acquisition sequences (defined as scenario) can contain infinite loops allowing continuous measurements. All the measurements can be stored in the database and can be monitored from anywhere at any time by remote access. The acquisition software is based on Labwindows/CVI. The Following components were required for the software configuration of the ERAS setup: Labwindows/CVI 5.5.1, NiVisa 2.01, Niswitch 1.5, IVI Engine 1.6 and NI-DAQ 6.9.

#### **4.1.4 VACUUM PUMP**

A Vacuum pump was used to evacuate the model. The pump has a vacuum pressure gauge ranging from a maximum pressure of 1200 mbar to a minimum of 0-mbar. The vacuum pump along with a fluid displacement pump was also used to saturate the model with fluids.

#### **4.1.5 VOLUME MEASURING DEVICES**

Graduated cylinders of various volumes were used to collect and determine the volumes of injected and produced fluids.

#### **4.1.6 AUXILIARY EQUIPMENTS**

The Fann Resistivity Meter (model 88c) was used to measure brine resistivity. The Terratek Resistivity Meter was also used for the resistivity measurement of the saturated porous media.

An MPH I-220 Helium Porosimeter was used to measure the porosity of the porous medium.

The Viscosities and densities of kerosene and brine were measured using a viscometer and a hydrometer, respectively.

A manual polyethylene sprayer pump was used to inject brine in the model when the flow rate achieved by gravity was very low. The sprayer pump was pressurized to 1 bar.

Fittings and valves, weighing balances, pressure gauges, a potentiometer, an ammeter, resistivity arrays, and a manometer were also used at different stages of the experiments.

#### **4.1.7 NUMERICAL MODEL**

A mathematical model developed by Schlumberger was validated and then used to analyze experimental data. The model can be used to simulate a reservoir with water movement in any direction after a little modification of the input file used to provide the required inputs for the model. The geometrical description of the reservoir is entered in cylindrical coordinates. Electrodes are located at the nodes of the grids. To get the potential distribution using the numerical model, it is necessary to define the position of the fluid front and also the resistivities of different fluid zones.

## 4.2 FLUIDS AND POROUS MEDIA USED

### 4.2.1 FLUIDS

Oil and brine were used to simulate zones of high and low resistivity. Due to a limitation of the acquisition system towards the high values of impedance, it was necessary to choose the water salinity and oil viscosity so that when brine was displaced with oil, residual brine saturation was high enough to generate conductivity that was within the limits of the acquisition system. At the beginning of this study, mineral oil with high viscosity represented the oil phase. When it was injected in the model, it displaced almost all the water from the porous media leaving a highly resistive zone behind, which exceeded the limits set for the acquisition system. Several combinations of oils were tested before selecting pure kerosene to represent the oil phase. Brine with a concentration of 200,000 ppm was used to represent the conductive medium. Green coloring was added to the brine to show the movement of the water phase in the model (Figure 4.2.1). The color was insoluble in kerosene and did not stain the porous media, which helped to distinguish the water phase from the oil phase (Figure 4.2.2). The specific gravity of kerosene used was 0.78 and viscosity was 1.27 cp, and the specific gravity of the brine was 1.154 (after the addition of color) and its viscosity was 1.67 cp. All the measurements were conducted at room temperature (about 24 degrees Celsius).

**Figure 4.2.1: Photograph of Fluid Front as Seen From the Side of Sector Model (front view).**

**Figure 4.2.2: Photograph of Fluid Front as Seen From the Side of Sector Model (side view).**

#### **4.2.2 POROUS MEDIA**

Glass beads were used to represent the porous media in the physical models. Only spherical beads that passed a 30-mesh screen and retained by a 40-mesh screen were used for this experiment. Good packing of the porous media was assured through the use of a large electric vibrator. After a few hours of continuous vibration, the level of the glass beads went down indicating compaction, after which more glass beads were added and vibration was continued. The total requirement of glass beads to fill the model was about ninety kg. After filling the model, the top cover was attached carefully to the bottom plate using nuts and bolts with screws to avoid any leaks (Figure 4.2.3).

Porosity and permeability were selected to cover the practical scaling criterion. The porosity measurement of the pack was based on the volumetric method, which involves the measurements of both bulk, and pore volume.

To measure the porosity of the glass beads pack, the measurement cup of the Helium Porosimeter was filled with the metal disks (the billets) and also with the glass beads and vibrated to compact the beads. The average porosity obtained from the Helium Porosimeter was 37.5%.

A tube packed with the same glass beads was used to measure permeability based on Darcy's law. The absolute permeability at 100% water saturation was 128 Darcys keeping the tube at horizontal position. A water manometer was used to achieve good accuracy in measuring the differential pressure for this high permeability.

**Figure 4.2.3: Photograph of Sector Model on the Vibrator.**

## **4.3 EXPERIMENTAL PROCEDURES**

### **4.3.1 PROCEDURES FOR THE CYLINDRICAL MODEL**

The cylindrical model was used to select the best combination of oil-water to be used in the sector model to conduct the experiment. It was also used to measure the resistivity of the different fluid zones to use as an initial input for the numerical model.

In the cylindrical model, the two metallic connectors at each end were used as the current electrodes for measurements of resistance. Eleven electrodes, 3 cm apart were used for the measurement of potential drop, which is defined as a 4-point measurement (Figure 4.1.4).

The model was first filled with brine, which was replaced with kerosene to get the connate water saturation and again brine was injected from the bottom to get the residual oil saturation. The electrodes of the both arrays were connected to the central control unit with copper wires and used for measurements of potential drops for all the displacements. Resistances were measured to observe the movement of water in the model. Measured Resistances varied significantly with change in resistivity of oil saturated and brine saturated zones.

**Figure 4.3.1: Photograph of Cylindrical Model With the Accessories.**

#### **4.3.2 PROCEDURES FOR THE SECTOR MODEL**

The experimental procedures for the sector model were divided into two parts. Firstly, the experiment was conducted keeping the model in an upward position (the well and its electrodes remained at the top) as it is shown in Figure 4.3.2 and secondly, to simulate an injection well, keeping the model in an inverted position (the well and the electrodes remained at the bottom) as it is shown in Figure 4.3.3. The sharp end of the sector model did not allow appropriate compaction when the model was in the upright position. Due to low compaction, water saturation was locally very low, which increased the local resistivity and limited the injection of electric current when the model was saturated with oil at connate water saturation. So, the model was inverted to have a better contact of the electrodes with the porous media to improve the quality of the measurements. The experiment was divided into seven parts referred to as seven cases. The first two cases were conducted keeping the reservoir model in an upward position and the next three cases were conducted keeping it in an inverted position. The last two cases were conducted by tilting the radial model to an angle of 25 degrees from the vertical axis. Before starting the actual experiment, the physical properties of the model were measured to determine different parameters associated with the experiment and the resistivity measurement.

**Figure 4.3.2: Photograph of the Sector Model With ERAS.**

**Figure 4.3.3: Photograph of Sector Model While Inverted.**

For the first part of the experiment, the following procedures are applied:

**4.3.2.1 MEASUREMENTS OF PHYSICAL PROPERTIES:**

1. The sector model was cleaned properly and vibrated after filling to get a packing similar to a compact reservoir. Then, air was evacuated from the model for several hours until the vacuum pump read close to absolute zero pressure.
2. Brine with a concentration of 200 kppm was injected to saturate the pack until a steady state condition was reached. The total volume of brine required to fill the model was 22.3 liters.
3. The bulk volume of the sector model was calculated using the dimensions of the model before filling it with glass beads. The bulk volume of the model was 59.2 liters. Brine required to fill the pores of the triangular model was 22.3 liters from which the calculated porosity was 37.67%, which is close to the one obtained using the Helium Porosimeter (37.5%).
4. Kerosene was then injected into the water-saturated model until no more water production was observed. At this stage the connate water saturation was calculated. 20.6 liters of water were recovered at the end of injection in the model and the calculated connate water saturation was 8.04 percent.
5. Brine was again used to displace the kerosene from the model to calculate the residual oil saturation in the model. The amount of injected kerosene was 20.6

liters and recovered kerosene during displacement was 17.9 liters. So, the calculated residual oil saturation was 13.1 percent.

#### **4.3.2.2 RESISTIVITY MEASUREMENTS**

An array of electrodes was inserted in the main well and another set of electrodes was inserted later with two reference electrodes located on the surface to inject current and to measure the potential drops with respect to each of the array electrodes. Measurements were conducted using both sets of electrodes at different stages of kerosene injection in the model and also at different stages of kerosene displacement with water to facilitate the comparison of resistances obtained in the two situations, which helped to check the accuracy of resistance measurement. Two reference electrodes were placed at the other end of the sector model. Current was injected through the first electrode of each array (source electrode) with respect to one of the reference electrodes and the potential drop was measured using the other electrodes of the array with respect to the other reference electrode. Potential was measured between the reference electrode and only one electrode located in the array each time (Figure 4.3.4). The same resistance measurement procedure was repeated for the rest of electrodes.

A central control and acquisition unit, defined as Electrical Resistivity Array Software (ERAS), was used to facilitate the operation and control of the associated electrical equipment. The electrical current to the source electrode, return current potentials from the monitoring electrodes, and tuning of the signal generator, were all provided through

the control unit. ERAS consists: a signal generator module capable of providing a wide variety of frequencies and wave-forms, a digital multi-meter module, and an oscilloscope unit capable of monitoring two signals simultaneously--current signal and potential signal.

Another type of measurement was tried to detect the water front movement in the reservoir, defined as a 4-point measurement. For this case, the potential drop was measured between the last electrode and any other electrode of the same electrode array. The potential drops were then connected by isopotential lines on a map of the model reservoir to yield maps of the potential distributions within the reservoir. As there was a sufficiently large resistivity contrast between the hydrocarbons and water zones, the water front movement or water table rise caused a significant deflection in the isopotential lines indicating the advancement of the water front (Figure 4.3.5).

**Figure 4.3.4: Measurements Using Array of Electrodes and Reference Electrode.**

**Figure 4.3.5: 4-point Measurement Without Reference Electrode.**

#### 4.4 ANALYSIS OF RESISTIVITY MEASUREMENTS

In the experiment, we obtained the potential drop knowing the position of the front. In practice, we are interested in the inverse problem: Can we deduce the position of the interface (resistivity distribution) from the potential distribution.

The classical procedure to solve the inverse problem can be described as follows:

Let  $F$  be the direct model allowing one to compute the distribution of potential in the reservoir for a given set of model parameters  $P$  (resistivity, position of electrodes).

Let  $F(P) = V(z)$ , be the potential distribution and  $P_o$  be an initial Potential distribution.

Neglecting second order terms we can write,

$$\left( \frac{dF}{dP} \right)_{P=P_o} = \frac{F(P) - F(P_o)}{P - P_o} \quad \text{.....Equation 4.1}$$

This can be re-written as:

$$\left( \frac{dF}{dP} \right)_{P=P_o} \times (P - P_o) = F(P) - F(P_o) \quad \text{.....Equation 4.2}$$

Where:

- $P$  is the set of unknown parameters (resistivity distribution),
- $P_o$  is the initial guess of parameters, (known)
- $F(P)$  are the measured potential, (known)
- $F(P_o)$  are the calculated potentials for the initial set of parameters  $P_o$  (known).

The term  $dF/dP$ , called the sensitivity matrix or Jacobien matrix expresses the sensitivity of the measurements to each parameter. Each term of this matrix can be computed using 2 runs of the direct model.

The equation has the form of  $\underline{A} * \underline{X} = \underline{B}$ . Where,  $\underline{A}$  is the sensitivity matrix,  $\underline{X}$  is the unknown vector of parameters and  $\underline{B}$  is the vector expressing the difference between the measured and computed potentials. This matrix equation can be solved using classical techniques available in the literature (references 23 and 24). Detailed description of the solution is out of scope of this study.

Fortunately, in our simple case, the number of unknown parameters is only 1, and a trial and error procedure was sufficient to invert the problem.

The following procedure was used to determine the position of the fluid front from the potential measurements:

1. Run the simulation software with an approximate value of the front position.
2. Visualize the difference between the measured potentials and the computed ones.
3. Guess from the sign of the difference in which direction the front must be moved.
4. Run the simulation software with this new value.
5. Iterate the process (2) until the difference is below the measurement noise.

The resistivities of the fluid zones in the model were inserted as the inputs to the numerical model to obtain the apparent resistances for different front distances. To

calculate the resistivity of different fluid zones, the cylindrical model was used, and was packed using the same procedure to obtain the same reservoir characteristics.

For the second part of experiment with the sector model only, the displacement procedure was followed inverting the model in the opposite direction, as the physical properties were known earlier. The model was again flushed with brine (12 pore volumes of brine were circulated) to remove all the residual oil obtained from the previous oil injection and to get almost 100% brine saturation before inverting it for measurement of resistances from an injection well. The model was physically put upside down and the well was located in this case at the bottom along with the electrodes. The brine was displaced with kerosene to get the connate water saturation and, subsequently, brine was re-injected to displace the kerosene similar to the case of a water injection well. Again, (for only one case) the brine was displaced with kerosene similar to the case when water is produced from injection well to measure the relative permeabilities. Three sets of measurements (three cases) were conducted using the two sets of electrodes while displacing brine, oil and again brine.

Sensitivity of the numerical model to the movement of fluid and also to the change of resistivity of the fluid was calculated using different resistivity values for different fluid phases and also using different fluid front positions as the input for the numerical model.

# *Chapter 5*

## ***INTERPRETATION OF RESULTS AND DISCUSSION***

## **CHAPTER 5**

### **INTERPRETATION OF RESULTS AND DISCUSSION**

#### **5.1 EXPERIMENTAL RESULTS AND DISCUSSION**

Experiments were conducted in the sector model and also in the 1D cylindrical model. The main experimental results were obtained using the sector model. The results obtained were used to validate the mathematical model.

##### **5.1.1 CYLINDRICAL MODEL**

Before starting experiments with the large sector model, it was necessary to observe the change in resistances due to changes in fluid content and to understand the measurements in a small model. The small cylindrical model was used to select the best combination of oil-water to be used in the sector model. The acquisition system used for this experiment had a limitation in measuring infinite resistance. So, there was a need to optimize the combination of fluids used in order to get the maximum resistivity contrast between the oil and water phase within the limit of the acquisition system. The cylindrical model was also used to get the resistances implied by different fluid phases.

Knowing the geometric factor for the cylinder, resistivities for different fluid phases were calculated from those resistance data and the resistivities were used in the numerical model as an input for the initial resistivities of different fluid phases in sector model.

Current was injected using the electrodes at each end of the cylinder and the electrodes mounted along the model were used to measure the resistance with respect to a reference electrode placed at the bottom of the model. The electrodes in the array were placed three centimeters apart and completely penetrated across the diameter of the media from one end to the other. Measurements were also conducted using pairs of electrodes while one fluid was injected in the model from one end and another fluid was produced from the end. As the geometric factor for the cylinder was known, resistivities for different fluid zones were calculated from the measurements. Several combinations of oil and water were used in the model before going for the selection of kerosene and 200,000 ppm brine for the experiment.

Measurements made with the cylindrical model greatly helped to understand the different factors controlling of the measurements and it was possible to correlate the position of the fluid front in the cylinder directly with the measurements. Those measurements were divided into two cases (Figure 5.1). At first (Case A), the cylinder was 100% saturated with brine and then oil was injected from the top to reach connate water saturation. In Case B, brine was injected from the bottom to simulate upward water-oil contact movement. In both cases, resistances were measured at different front positions and were shown in Figure 5.2 and 5.3, respectively.

**Figure 5.1: Block Diagram of Different Cases for the Cylindrical Model.**

#### **5.1.1.1 CASE A**

##### **Injection of Oil in the 100% Water-Saturated Cylindrical Model:**

The objective of this run was to make a series of injections into the top of the brine saturated cylindrical model to reach connate water saturation. After each injection, time was allowed for the fluids to reach equilibrium and to clearly visualize the front. At each equilibrium stage, the resistances were measured.

Results obtained from this run are presented in figure 5.2. The inset at the top shows the oil-water interface at different positions relative to the potential electrodes in the cylinder. From the results obtained from this experiment, it was possible to correlate the behavior of resistance directly to the position of the front.

#### **5.1.1.2 CASE B**

##### **Injection of Brine in the Cylindrical Model at Connate Water Saturation:**

The objective of this run was to simulate water displacing the oil from the bottom of the cylinder to get the residual oil saturation. This kind of phenomenon is often observed in producing wells. The measurements gave an idea about the change in resistance due to water encroachment and also described the resistivity of the different fluid phases. Results are presented in figure 5.3. The inset shows different front positions in the cylinder for the measured data with the same color.

Figure 5.2 Resistances Measured at Different Electrode at Different Fluid Front Position for Case A.

### **5.1.2 SECTOR MODEL**

In the sector model, one set of electrodes was mounted on the main well to simulate the actual permanent downhole electrodes arrangement. That set contained 31 electrodes (1 cm apart from each other) and was defined as the first set of electrodes. However, to have a better control on the position of electrodes and due to contact problems with the porous medium, a new set of electrodes was inserted in the porous medium in a line parallel to the well and at a distance of 1.5 cm from the well. This set was defined as the second set of electrodes and it contained 18 electrodes (1.5 cm apart from each other). Experiments were conducted in the model using both sets of electrodes. In each set, the first electrode was used as the current injection electrode and the others were used for resistance / potential drop measurement. Initially, the model was kept in a vertical position (sharp end with the well and the electrodes are at the top) and the injection of fluids and measurements of resistance were conducted in the model as it is done for an oil producing well in a reservoir. Later, the model was kept in an inverted vertical position (sharp end with the well and electrodes at the bottom) to have a more compacted porous media in the vicinity of the electrode arrays. Measurements made in this condition represented the measurements from an injection well in the reservoir. Also, experiments were conducted keeping the model in an inclined position (25 degree-angle from the vertical axis) to observe the effect of front orientation on the measurements. For an easy understanding of all the measurements made in different measurement conditions, the

experiments were divided into seven cases. Those seven different cases are shown in figure 5.4 and 5.5. The cases are summarized below:

1. **Case 1:** Injection of oil in the brine-saturated model from the top keeping the sharp end at the top to obtain connate water saturation for a producing well.
2. **Case 2:** Injection of brine in the oil-saturated model from the bottom keeping the sharp end at the top to obtain residual oil saturation, which will represent water encroachment to an oil producer.
3. **Case 3:** Injection of oil from the top in the brine-saturated model keeping the sharp end at the bottom to obtain connate water saturation for an injection well.
4. **Case 4:** Injection of brine in the oil-saturated model from the bottom keeping the sharp end with the electrodes at the bottom to obtain residual oil saturation, which represents a brine injection well.
5. **Case 5:** Re-injection of oil from the top in the brine injected model with residual oil keeping the electrodes at the bottom. This represents the injection well used to calculate the relative or end point effective permeability of both the brine and oil bearing media in the vicinity of the injection well.
6. **Case 6:** Injection of oil from the top in the brine-saturated model keeping the sharp end at the bottom when the model was tilted at an angle of 25 degrees to the vertical axis to obtain connate water saturation.

7. **Case 7:** Injection of brine from the bottom in the oil-saturated (at connate water saturation) model to obtain residual oil saturation when the model was in the tilted position as in case 6.

While conducting the experiments, there were some errors introduced due to the displacement of electrodes in the first set of electrodes. From the Theory of Electricity Flow, it is known that the potential drop is inversely proportional to the distance from the current injection source and the same proportion was found for error calculation. Calculated error was found to be maximum for the closest electrode to the current injection electrode and decreased with distance. It was the minimum for the furthest electrode from the current injection electrode. For a 2 mm displacement of the electrode in the sector model, the error in measurement was more than 40 percent for the first electrode and it decreased to 1.2 percent for the farthest electrode.

Accordingly, it was decided to exclude all the results from the analysis with an error of more than two percent. So, measurements made with the first 13 electrodes of the first set were excluded from the analysis and the other 18 electrodes were used to compare with the numerical ones. The behavior of error introduced for a displacement of 2 mm is shown in figure 5.6.

**Figure 5.4: Cross-sectional Schematic for Cases 1 to 4.**

**Figure 5.5: Cross-sectional Schematic for Cases 5 to 7.**

**Figure 5.6: Error Introduced in Measurements for a Displacement of Electrode Position for 2 mm.**

### **5.1.2.1 CASE 1**

#### **Injection of Oil in the Brine-Saturated Model:**

**CASE 1**

At the beginning, the model was 100% saturated with brine with a concentration of 200,000 ppm. Oil was injected to displace the brine and to obtain connate water saturation. Oil was injected in the model in stages with an equilibrium time of about 30 minutes between each injection stage. After visual detection of the oil-water interface at the end of each equilibrium stage, resistances were measured using the ERAS system. A 0.02-ampere current was supplied between the first electrode of the array in the well and the reference electrode at the other end (surface) of the model. Resistances were measured at each of the potential electrodes of both of the arrays with respect to the other reference electrode.

To complete each set of measurements, almost 7 minutes were required. As indicated earlier and due to contact problems, the electrodes of the first set were not in good contact with the porous media. Accordingly, there were some errors introduced in the measurements of the first electrode, especially with those electrodes that were very close to the injection electrode. The measurements of such electrodes were excluded from the analysis.

After displacing water with oil, connate water saturation was calculated to be 8.04 percent. The water, which was produced, was collected to calculate the connate water saturation. The measurements at different front positions are plotted and presented in Figure 5.1.1 for the first set of electrodes (Case 1-a) and in Figure 5.1.2 for the second set of electrodes (Case 1-b). The first set of electrodes was not able to measure properly the change in resistance due to change in fluid content as the front approached a distance of 70 cm from the current injection electrode. The fluid front was not clearly detectable further than that distance using the first set of electrode. This might be due to the improper contact between the porous media and the first set of electrodes.

Figure 5.1.1: Resistances Measured at Different Fluid Front Position for Case 1-a.

Figure 5.1.2: Resistances Measured at Different Fluid Front Position for Case 1-b.

### **5.1.2.2 CASE 2**

#### **Injection of Brine in the Oil-Saturated Model:**

**CASE 2**

The model at this stage simulates a radial reservoir with a uniform porosity and permeability surrounded with an aquifer, which is producing oil using the producer at the center. In this case, brine was injected from the bottom of the reservoir model. Produced oil was measured to calculate residual oil saturation in the reservoir model at the end of the displacement.

As the waterfront approached the well, resistances were measured at different oil-water interfaces (water front) using both sets of electrodes. The potential drop was the maximum at the closest distances, and measurements were always erratic in the vicinity of the injection electrode (specially with the first set of electrodes). Measurements made with the electrodes too close to the injection electrode were excluded from the presentation.

Measurements were plotted and presented in Figure 5.1.3 for the first set of electrodes (Case 2-a) and in Figure 5.1.4 for the second set of electrodes (case 2-b). In both cases, erroneous measurements of the closer electrodes were excluded.

At the end of the run (Case 2) the calculated residual oil saturation was about 13.1 percent. Although the residual oil saturation was not constant all over the model due to the significant gravity force acting on the fluid, it was assumed to be uniform throughout the model.

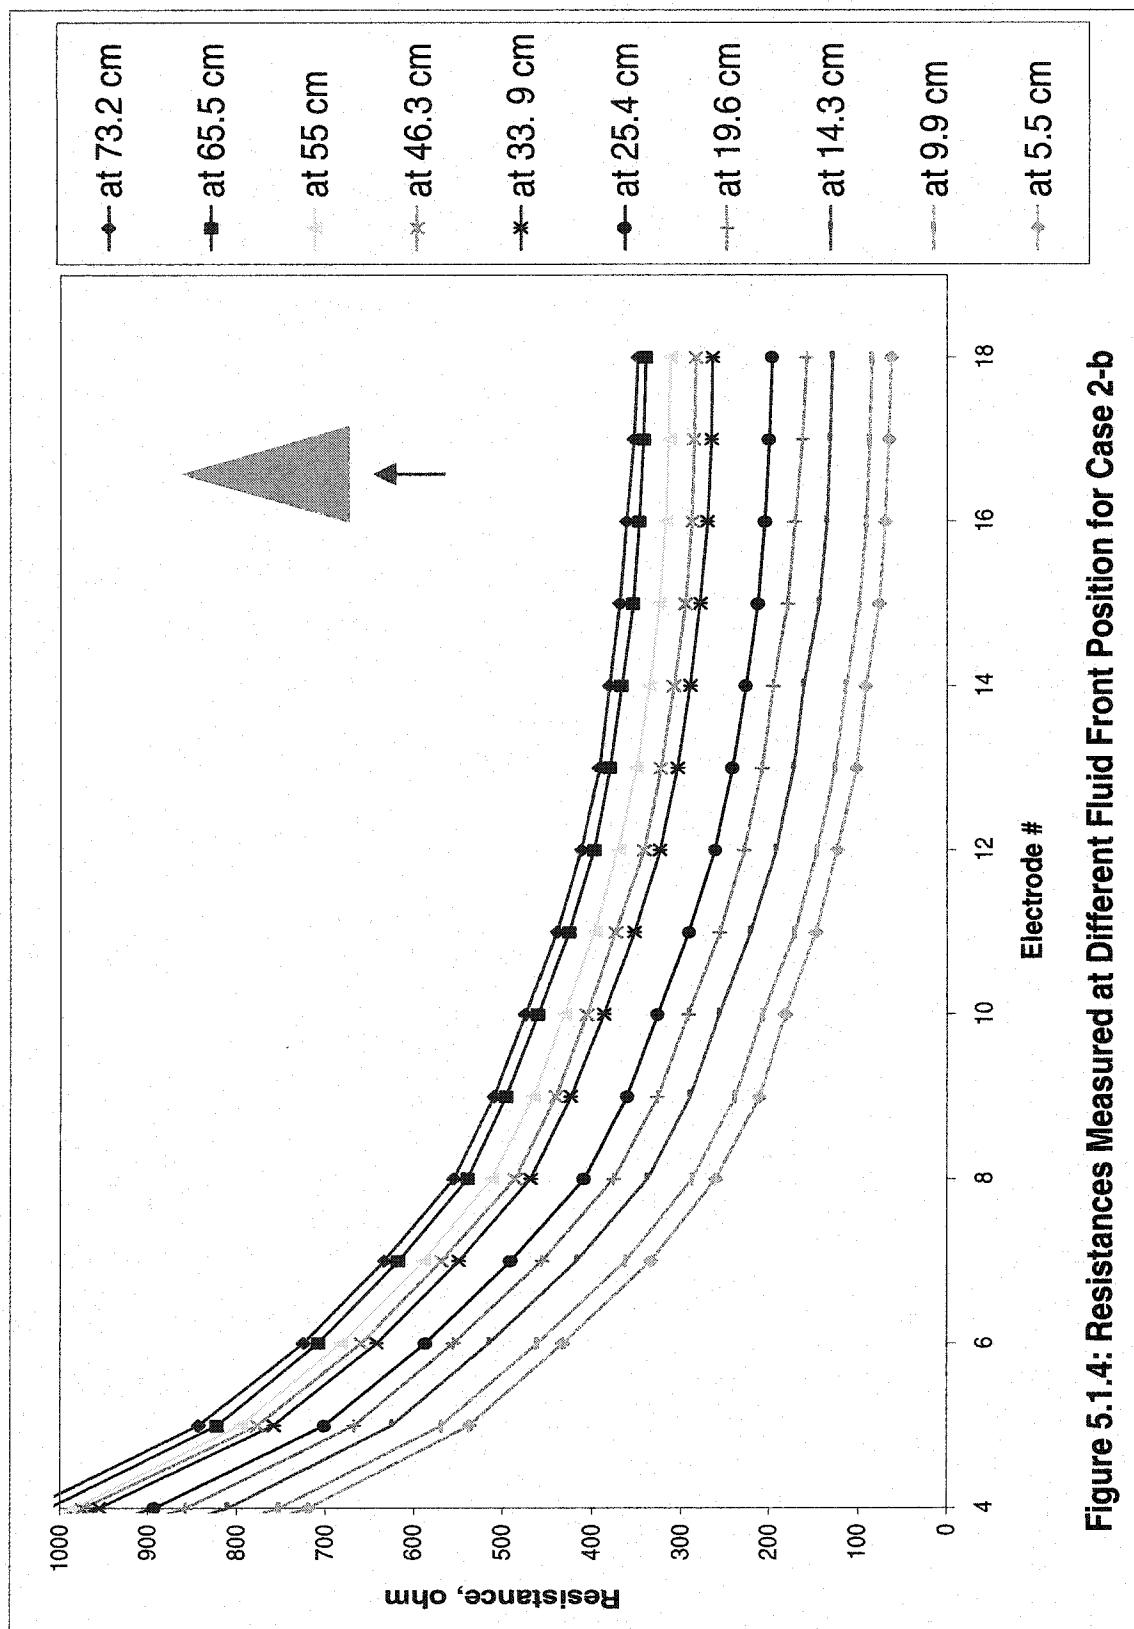

Figure 5.1.4: Resistances Measured at Different Fluid Front Position for Case 2-b

### **5.1.2.3 CASE 3**

#### **Injection of Oil in the Brine-Saturated Model:**

**CASE 3**

In this case, the reservoir model was vertically inverted with the well and electrodes at the bottom to get a more compacted porous media in the vicinity of the electrode arrays and to improve the measurements. Measurements conducted in this condition are completely different than those conducted in the previous cases as the environment of measurement is completely different.

Before starting the experiment, the model was flushed several times with brine at a high circulation rate to reduce residual oil saturation to the minimum. The circulation of brine was continued until no oil droplets were observed in the effluent. Almost 12 pore volumes of brine were needed to make the model almost fully water-saturated. The circulation rate was about 2-liters/ minute.

To obtain connate-water saturation, oil was injected in the model and resistances were measured using both sets of electrodes at different oil-water interfaces as it was done in Case 1. But here the electrodes were immersed in the water phase, which is just opposite

to the situation in Case 1. Therefore, resistances measured in case 3 were very low compared to that of Case 1.

These measurements were far better than the measurements in Cases 1 and 2 as the main well was at the bottom and the electrodes mounted on the well were in good contact with the porous media. It was also easier to simulate the results obtained by all the electrodes, including the ones closer to the injection electrode as the injected current was very low in the brine media compared to when the electrodes were immersed mostly in the oil zone.

The results obtained are plotted in Figure 5.1.5 for the first set of electrodes (Case 3-a) and in Figure 5.1.6 for second set of electrodes (Case 3-b). It should be noticed here that the measurement condition for case 3 was completely different than that of Case 1 or Case 2. In Case 1 and Case 2, both of the sets of electrodes were immersed in the oil phase for most of the time and the change of potential was very high for each cm of fluid movement due to the high resistance of the oil zone. But for Case 3 and for the later cases the electrodes were immersed in conductive media and the change in potential due to fluid movement was completely different. So, for Case 1 and Case 3, there was a big difference in measurement conditions and measurements for one case are not comparable with the other. For the same reason, measurements made by ERAS in this case were faster than before.

Figure 5.1.6: Resistances Measured at Different Fluid Front Positions for Case 3-b.

#### **5.1.2.4 CASE 4**

##### **Injection of Brine in the Oil-Saturated Model**

**CASE 4**

This case started with the model at connate-water saturation. Brine was injected from the bottom to displace oil as it is done in an injection well. This run was conducted to monitor the change in resistances due to the advancement of the injection fluid. Obviously, mention that the measurement condition for this case is also completely different from that of Case 1 or Case 2.

The experiment was continued until residual oil saturation was obtained. Measurements conducted during this run were also faster using the ERAS system, as it was in Case 3.

The resistivity data were plotted in Figure 5.1.7 for the first set of electrodes in the well (Case 4-a) and in Figure 5.1.8 for the second set of electrodes (Case 4-b). If the measurements are compared with those obtained from case 2, it is found that the slope of the lines connecting each measurement point by each electrode are different for the two cases. This difference is also related to the measurement environment, as in case 4 the measurement environment is facing very low impedance compared to case 2.

Figure 5.1.7: Resistances Measured at Different Fluid Front Positions for Case 4-a.

#### **5.1.2.5 CASE 5**

**Re-Injection of Oil when**

**Model at Residual Oil Saturation:**

**CASE 5**

Although this case does not have any direct practical application in the field, this kind of experimental run could help in the determination of relative permeabilities in the vicinity of the injection wells in the field. To simulate those situations, oil was re-injected into the model when it was at residual oil saturation. The measurement condition was the same as it was for Case 3.

Resistances were plotted in Figure 5.1.9 for the first set of electrodes (Case 5-a) and in Figure 5.1.10 for the second set of electrodes (Case 5-b) as it is done in other cases. The results are almost similar to case 3, but the resistances are higher than those obtained in that case.

The quality of the measurements indicated that the electrodes were in good contact with the porous media and the smoothness of the data set indicates an easy injection of current in the conductive media.

Figure 5.1.10: Resistances Measured at Different Fluid Front Positions for Case 5-b.

#### **5.1.2.6 CASE 6**

##### **Injection of Oil in a 25-Degree**

##### **Tilted Model:**

**CASE 6**

The objective of this experiment was to observe the sensitivity of measurements to the change in front orientation. In this case, the model was tilted to an angle of 25 degrees from the vertical axis. Initially, the model saturation was restored to nearly water saturated, and then oil was injected in stages to simulate the advancement of the front.

After each injection cycle, the model was allowed to reach equilibrium and resistances were measured using the ERAS system. To allow comparison and to evaluate the effect of tilting on measurements, the same front positions were used as in Case 3.

The measurements are plotted in Figure 5.1.11 using the first set of electrodes only. Also the measurements of Case 3 are plotted to have a clear comparison with the measurements made by keeping the model at vertical position. From the measurements for each position it is clear that of fluid front orientation.

Figure 5.1.11: Comparison of Resistances Measured at Different Electrodes at Different Fluid Front Positions For Case 6 (solid line) and Case 3 (dotted line).

### **5.1.2.7 CASE 7**

**Injection of Brine in the  
Model Keeping the Model  
At an Angle of 25 Degrees  
To the Vertical Axis:**

**CASE 7**

The objective of this run was the same as it was for Case 6. Measurements made in this Case (Case 7-a: For injection of water and Case 7-b: For re-injection of oil) were compared to those results obtained in Cases 4 and 5.

The procedure was the same as it was in Cases 4 and 5, except the model was tilted at 25-degrees. The measurements at different front positions were plotted in Figure 5.1.12 for the injection of brine (Case 7-a) and in Figure 5.1.13 for the re-injection of oil (Case 7-b). In this case, the second set of electrodes was not used for measurements, as the results obtained from the first set were sufficient to observe the difference in measurement and also to compare with the measurements made in the vertical position. In all the cases, the difference in measurements was significant enough to signal the effect of the fluid front orientation on the measurements.

**Figure 5.1.13: Comparison of Resistances Measured at Different Electrodes at Different Fluid Front Positions For Case 7(b)(solid line) and Case 5 (dotted Line).**

## 5.2 NUMERICAL RESULTS AND DISCUSSION

The experiments conducted on the sector model were simulated using a numerical model developed by Schlumberger. Simulated results were compared to the experimental results. The model was approximated by a cylindrical grid system in three-dimensional coordinates. In order to generate resistances for each front position, the numerical model required the resistivities of different zones across the fluid front, the position of the fluid front, and the definition of the position of the electrodes as inputs.

The model is based on the Finite Element Scheme and is written in FORTRAN. The model is used to simulate water front movement in a radial direction in a cylindrical reservoir surrounded by an aquifer. This model can be easily used to simulate a reservoir with planar front movement after some modifications to the input files. It can also be used to simulate a waterfront approaching the well at an angle. The geometrical description of the reservoir is entered through the definition of a grid in cylindrical coordinates. The grid size is variable. Fine cell sizes are used in the vicinity of the borehole and much larger cells are defined near the border of the model. Electrodes are located at the nodes of the grids.

The program computes the potential distribution resulting from an injection of current between an electrode located on the axis of symmetry (the well) and a return electrode

located at infinity. From this potential distribution, apparent resistivities between any set of electrodes are computed further on. The program solves the DC current laws (can be used for AC current also at very low frequencies) as described by the equations below:

$$\vec{J} = \sigma \cdot \vec{E} \quad (\text{Ohm's law}) \quad \dots\dots\dots \text{Equation 5.1}$$

$$\vec{E} = -\vec{\nabla}V \quad (\text{Potential definition}) \quad \dots\dots\dots \text{Equation 5.2}$$

$$\vec{\text{div}}(\vec{J}) = \delta_{i,j} \quad (\text{Current preservation}) \quad \dots\dots\dots \text{Equation 5.3}$$

Where  $\delta_{i,j} = 0$  everywhere except at the source location where it is equal to J, the current injected.

Combining the above three equations yields:

$$\text{div}(-\sigma \cdot \nabla V) = \delta_{i,j} \quad \text{this is solved under the equivalent form:}$$

$$\nabla^2(-\sigma \cdot V) = \delta_{i,j} \quad (\text{Laplace equation}) \quad \dots\dots\dots \text{Equation 5.4}$$

Equation 5.4 is discretized at the nodes of the grids and solved using the finite element technique, the description of which can be found in reference 22.

To accurately determine the resistivity of the porous medium across the fluid front under different saturation conditions, the cylindrical model was used (Section 5.1.1). The model was filled with glass beads in the same manner as it was done for the sector model to obtain the same porous media. The cylinder was saturated with 200,000 ppm brine and the resistivity at this stage that was obtained by 4-pole measurement was used in the simulator to represent a 100% water saturated zone. With the change of fluid content in

the zone between each pair of electrodes in the cylindrical model, the resistances changed and the ratios of the new resistances to the old ones were used to get the resistivity.

There were seven electrodes on the top plate of the sector model. Each pair of electrodes measured the resistances of the saturated porous medium between the two electrodes. The resistances measured with the 7 pairs of electrodes (at the top plate) were used to simulate the sector model with different positions of oil-water interfaces. It was found that the potentials obtained from the sector model were 15.5 times higher than the simulated ones.

This factor is exactly the ratio of 360/23.3 of the sector model to the radial model (Figure 5.7). The difference in measurements is due to the fact that the numerical simulator assumes that the injected current flows in all directions whereas in the scaled model the injected current is only allowed to flow in the restricted path (unidirectional flow because the other ends were closed using non-conductive Plexiglas plates). Therefore, the calculated resistances were 15.5 times (i.e., 360/23.3) smaller than those of the experimental values. For this reason, resistances obtained experimentally were divided by a factor of 15.5 before comparing them with simulated values.

The sensitivity of the numerical model to the movement of fluid and to the change in resistivity of the fluid was calculated using different resistivity values for different fluid phases and also using different fluid front positions as the input for the numerical model. The sensitivity to the movement of the fluid front and to the change in resistivity across the fluid front was investigated and the average sensitivity with a 1 ohm-m change in the

resistivity of the oil phase was 0.34 V/ohm-m. The sensitivity due to a 1 cm movement of the fluid front varied from 3.5 V/cm to 1.35V/cm for a distance of 23 cm to 63 cm, respectively, while the resistivity for the oil phase was 80 ohm-m and the resistivity of the conductive medium was 0.18 ohm-m.

The sensitivities of the experimental and numerical data were also computed and comparisons of both the sensitivities are shown in Figure 5.8, which clearly indicates that with level of accuracy of our experiment and the hardware used, it is possible to detect the movement of a fluid front up to a distance which equals twice the thickness of the pay zone (the array span). The sudden drop in sensitivity after a distance of 60 cm from the well was due to the segregation of fluid due to gravity, since part of this experiment, in this case, was conducted in two stages separated by a waiting period of about 8 to 12 hours.

**Figure 5.7: Sector Model With an Angle of 23.3 Degree.**

Figure 5.8: Sensitivity (volts/cm) of the Measurements with Fluid Front Positions from the Measurement Well.

### 5.3 COMPARISON OF RESULTS

Comparison of the results obtained from the experimental and numerical methods are presented in this section. Cases 1 to 5 are considered for this comparison.

#### 5.3.1 CASE 1

**Injection of Oil in the  
Brine-Saturated Model:**

**CASE 1**

The description of this experiment was presented earlier in Section 5.1.1.1. However, the following is presented to highlight the reasons for differences encountered during numerical simulation.

The model was initially 100% saturated with 200,000 ppm brine. Oil was then injected to reach connate water saturation. During the oil injection, and due to low water saturation, the measured resistances suddenly increased to very high values and it was difficult to inject current using the first set of electrodes. With increasing oil saturation in the model, the resistances continued to increase considerably. As the oil-water interface

reached a distance of 70 cm from the measurement well, it was impossible to inject more than 0.1 mA, which is the limit to obtain reliable measurements from the acquisition system.

However, the above problem did not affect the simulated data. Moreover, comparisons of experimental and numerical results were difficult for the potential electrodes very close to the injection electrode as there was always some residual resistivity or local resistivity in the vicinity of the injection electrode. When the comparisons were made, results for those electrodes were excluded from the rest of the data points.

This kind of problem was significantly reduced using the second set of electrodes and the comparison was better. Comparisons of the experimental and numerical values for the first set of electrodes are shown in Figure 5.2.1 (Case 1-a) for all fluid fronts and also in Figure 5.2.2 for selected front positions. Figure 5.2.3 (Case 1-b) and figure 5.2.4 show the same results as obtained from the second set of electrodes.

Figure 5.2.1: Comparisons of Experimental and Numerical Results for Case 1-a.

**Figure 5.2.2: Comparisons of Experimental and Numerical Results for Selected Front Positions for Case 1-a.**

Figure 5.2.3: Comparisons of Experimental and Numerical Results for Case 1-b.

**Figure 5.2.4: Comparisons of Experimental and Numerical Results for Selected Front Positions for Case 1-b.**

### **5.3.2 CASE 2**

#### **Injection of Brine in the Oil Saturated Model:**

**CASE 2**

Before presenting the numerical results for this case, it is important to understand the experimental conditions because they have significant impact on the comparison of the two results.

Almost two days were required to conduct the experiment described in Case 1. During this time, there was segregation of oil and connate water due to the force of gravity and high permeability. Based only on visual inspection, the uppermost zone seemed almost water-free. This situation adversely affected current injection as the zone in the vicinity of the injection electrode was almost non-conductive and some of the electrodes were not in good contact with the media and were completely immersed in oil. Accordingly, there were some errors in the measurements based on the first set of electrodes, especially in the vicinity of the injection electrode. For this reason, the closest points (almost 13 cm) to the injection electrode were excluded from comparison with the simulated data. Also, for distances more than 75 cm from the production well, the resistances were too high to measure using the first set of electrodes.

This kind of problem was also found for the second set of electrodes, but it was not as severe. It was possible to detect further than 75 cm using the second set of electrodes as the measurements had less noise interference and were more sensitive. Comparisons for the first set of electrodes are shown in Figure 5.2.5 (Case 2-a) and also in Figure 5.2.6 for selected front positions. Figure 5.2.7 (Case 2-b) and in Figure 5.2.8 present the same results using the second set of electrodes.

Figure 5.2.5: Comparisons of Experimental and Numerical Results for Case 2-a.

Figure 5.2.7: Comparisons of Experimental and Numerical Results for Case 2-b.

Figure 5.2.7: Comparisons of Experimental and Numerical Results for Case 2-b.

**Figure 5.2.8: Comparisons of Experimental and Numerical Results for Selected Front Positions for Case 2-b.**

### **5.3.3 CASE 3**

#### **Injection of Oil in the 100% Brine Saturated Model:**

**CASE 3**

Because of the problem in measurements due to the lack of good contact between electrodes and the porous media and due to fluid segregation, the reservoir model was inverted vertically with the well and electrodes at the bottom to assure more compacted porous media in the vicinity of the well. This approach improved the quality of measurements considerably.

The measurements made in this case, with the injection of oil from the top into the brine-saturated model, and displacement of brine at different oil-water positions were also simulated using the numerical model. Very good matches of the experimental and numerical results were obtained for almost all the electrodes except the first potential electrode using both sets. The first electrode of each set was the injection electrode and therefore, there was always some deflection in measurement due to the presence of high local resistivity in the vicinity of the injection electrode.

Comparisons for the first set of electrodes are shown in Figure 5.2.9 (Case 3-a) and for the second set of electrodes in Figure 5.2.10 (Case 3-b).

Figure 5.2.9: Comparisons of Experimental and Numerical Results for Case 3-a.

Figure 5.2.10: Comparisons of Experimental and Numerical Results for Case 3-b.

#### **5.3.4 CASE 4**

##### **Injection of Brine in the Oil-Saturated Model:**

**CASE 4**

Initially the model was saturated with oil at connate water saturation. Brine was injected from the bottom. A very good match was obtained between the numerical and experimental data.

Comparisons for the first set of electrodes are shown in Figure 5.2.11 (Case 4-a) and for the second set of electrodes in Figure 5.2.12 (Case 4-b). Change in resistance was the highest in the first electrode because it was used as the current injection electrode. Measurements at other electrodes were not that as sensitive to the position of the electrode as the arrays were in highly conductive media.

Figure 5.2.11: Comparisons of Experimental and Numerical Results for Case 4-a.

Figure 5.2.12: Comparisons of Experimental and Numerical Results for Case 4-b.

**5.3.5 CASE 5****Re-Injection of Oil in the  
Model at Residual Oil Saturation:****CASE 5**

In this case, oil was re-injected into the inverted model from the top. A very good match was obtained between the numerical and experimental data as shown in Figure 5.2.13 and Figure 5.2.14 for the first set and the second set of electrodes, respectively.

Figure 5.2.13: Comparisons of Experimental and Numerical Results for Case 5-a.

Figure 5.2.14: Comparisons of Experimental and Numerical Results for Case 5-b.

## 5.4 SUMMARY OF DISCUSSION

The results presented in this work, clearly show that the change of electrical potential due to the displacement of fluid front in a reservoir can be measured. Using the procedures described in this experiment, the fluid front position was detectable up to a distance of twice the length (span) of the electrodes array. Improvement of the measurement accuracy directly translates into an increase of this distance. This can only be done once the actual nature and level of the noise has been characterized. In this study, the noise was exclusively coming from the acquisition system and more especially from its limitation to perform correct measurements in very high impedance environments (created from improper contact of the electrodes with the porous media). This problem is less pronounced in the actual reservoirs. In a field experiment, the noise will have two origins:

- Industrial noise (essentially power supply)
- Natural noise from solar activity

Concerning the first one, the only thing that can be done is to operate at frequencies far from the power supply frequencies (50 and 60 Hz). As for the second source, the best which can be achieved is to operate at frequencies located around the known minimum energy of the natural electrical activity (1-10 Hz) and to use long integration times for the cross-correlation between the source signal and the measured one (lock-in amplifier).

It was also shown that the fluid front position can be detected using measurements from a single well, whether it is an injection or a production well, despite the fact that the measurement conditions (electrodes in brine or in oil) are totally different.

This work was aimed at showing that fluids fronts can be detected and it was not attempted so as to investigate the full inverse problem consisting of deducing from the measurements the exact position of the front. In the very simple case that was treated, there was no need to deal with all the controlling parameters (resistivity and geometry). In an actual case, where the number of unknown parameters is certainly much larger (vertical layering, mixed salinity, noise, etc), the inverse problem is more complex and more measurements are needed to limit the number of possible solutions. One way to increase the number of independent measurements is to use quadru-pole measurements having different vertical extensions. These types of measurements, extensively used in surface exploration, allow one to access resistivity of formation at different lateral distances from the well. This could form the subject of further work.

## *Chapter 6*

### ***CONCLUSIONS AND SUGGESTIONS***

## **CHAPTER 6**

### **CONCLUSIONS AND SUGGESTIONS**

#### **6.1 CONCLUSIONS**

Considering the questions asked at the end of chapter one, it could be concluded that:

1. Using a simple electrical method in a scaled model reservoir, it was shown that the displacement (location) of an oil/water front could be detected.
2. Interpretations of the measurements were very easy due to the presence of a minimum number of measurement factors.
3. As the front is detectable,
  - a. The maximum distance at which the detection can be reliable depends on the resistivity contrast and on the accuracy of the measurements. In this case, one can safely say that it is possible to detect a front located at a distance of 2 times the thickness (span of the electrodes) of the reservoir.
  - b. The technique is very sensitive to the position of the fluid front (potential changes by several tens of mV for a displacement of 1 mm).

- c. The measurements of resistance or potential drop between electrodes are very simple and can be interpreted easily.
  - d. By increasing the accuracy of the measurement down to a few microvolts, the maximum distance at which fluid movement is detected can certainly be increased by a factor of 2 or 3.
4. A mathematical model was validated and used successfully to reproduce the experimental data and also to study the various parameters (resistivity of fluid phase, position of front) influencing the measurements.
  5. The mathematical model can calculate the change in the potential distribution with the movement of the fluid front position using any electrode in the array with respect to a reference electrode. The model uses only the position of the front and electrodes and the resistivities of different fluid phases as inputs.
  6. The numerical model can be used for simulation of any form of fluid movement in a reservoir after a little modification in the input file.
  7. With the collected data (using one injection electrode and measurement of potential along an array), it is not possible to delineate the shape of the fluid front approaching the well. This was nevertheless verified that when the model was inclined. However, the measurements clearly reflect change due to the inclination of the front. By taking more measurements (increasing the number of source positions), a simple front orientation can be reconstructed.

## 6.2 SUGGESTIONS FOR FURTHER WORK

In this study, a number of assumptions and simplifications are made, which may not always be consistent with real field cases. Below is a non-exhaustive list of points that must be considered and whose influence can be tested using the same kind experimental of setup:

- a. In most flooding operations, the salinity of the injected water is, in general, different from the reservoir water. In practice, the front will most probably be characterized by a gradual change of resistivity rather than by a sharp contrast. The characteristics of the “buffer zone” are unknown and can probably be simulated by the scaled model.
- b. Due to time constraints, measurements were limited to a single source in a “single well” type of measurement condition. Clearly, results can be improved by using, firstly, several current sources, and secondly, cross-well experiments.
- c. Fronts are not likely to be perfectly horizontal / vertical; more work is required in order to assess the possibility of describing the shape and orientation of the front.
- d. In this study, the reservoir was very simple (uniform permeability and porosity) and was easy to interpret the experimental data. In practice, the interpretation of the measurements will certainly be less straightforward. Introduction of heterogeneities (variations in permeability or porosity) can also be studied.

- e. The assessment of doing similar measurements in deviated wells is also worth considering.
- f. The same experiment can be transposed to the fields.
- g. The numerical model can be validated for planar front movement or inclined advancement of water to the well.

The following recommendations are related to the experimental setup.

1. Glass beads of smaller size should be used to obtain more realistic permeability and irreducible water saturation.
2. Similar laboratory experiments can be used for gas reservoirs undergoing water drives.
3. The fluid front movement can be monitored using similar setup for deviated wells.

## NOMENCLATURE

$\phi$	Porosity, fraction
k	Permeability, mili-Darcy
cm	Centimeter
ppm	parts per million
cp	Viscosity in Centipoise
$\Omega$	Ohm,
$\Omega$ -m	Ohm-meter
J	Current Injected, ampere
V	Potential Distribution, volts
E	Change in Potential, volts
$\sigma$	Resistance in ohm
$\nabla$	Delta / Gradient
$\delta$	Current Distribution.

# *Appendix A*

## ***EXPERIMENTAL DATA***

## **APPENDIX A**

### **EXPERIMENTAL DATA**

Apparent resistances measured for different fluid front positions for the 7 cases previously described are presented in the following tables. Resistivity measurements were also performed using the classical 4-point technique. The results obtained by this method were affected by a large noise due to bad contact between some electrodes and the media. Consequently, these results were excluded from the results of this experiment. Two of them are nevertheless presented here as an example in Figure A.4.1 and Figure A.4.2.

Table A.1: Experimental Resistances for case 1-a.

## ***CALCULATIONS OF PROPERTIES***

## APPENDIX B

### CALCULATIONS OF PROPERTIES

#### B.1 PERMEABILITY MEASUREMENT

Permeability was calculated on the basis of Darcy's law. A cylindrical Plexiglas model was used to measure the permeability of the porous media. According to Darcy's law:

$$q = -\frac{kA}{\mu} \cdot \frac{\Delta P}{\Delta x} \dots\dots\dots \text{Equation - B.1}$$

$$k = -\frac{\mu q}{A} \cdot \frac{\Delta x}{\Delta P} \dots\dots\dots \text{Equation - B.2}$$

where, q is the flow rate in cc/sec, k is the permeability in Darcy,  $\mu$  is the viscosity in cp, x is the distance traveled by the fluid (x=L in our case), and  $\Delta P$  is the pressure drop along the path. Expressing the permeability in md, equation - B.2 can be written as:

$$k = \frac{\mu q L}{A \Delta P} \cdot 10^3 \dots\dots\dots \text{Equation - B.3}$$

For the set-up used, the following numerical values were there: viscosity: 0.9 cp, Length of the Cylinder: 53 cm, Diameter of the Cylinder: 3.98 cm, besides, 30 cc of brine was collected during 96 second. The manometer read 0.7 cm -, which is equivalent to a pressure of 0.1354-psi From equation – A.3 we obtained a permeability of 128.86 Darcy.

### POROSITY CALCULATION

Equations used for the Helium Porosimeter:

$$V_{REF} = \frac{V_{BR}}{\left( \frac{P_{REFFULL} - P_{ZERO}}{P_{CUPFULL} - P_{ZERO}} \right) - \left( \frac{P_{REFREM} - P_{ZERO}}{P_{CUPREM} - P_{ZERO}} \right)} \dots\dots\dots \text{Equation – A.4}$$

$$V_{DEAD} = \left[ \left( \frac{P_{REF} - P_{ZERO}}{P_{DV} - P_{ZERO}} \right) - 1 \right] V_{REF} \dots\dots\dots \text{Equation – A.5}$$

$$V_{TOTAL} = \left[ \left( \frac{P_{REF} - P_{ZERO}}{P_{TOTAL} - P_{ZERO}} \right) - 1 \right] V_{REF} \dots\dots\dots \text{Equation – A.6}$$

$$V_{PORE} = V_{TOTAL} - V_{DEAD} \dots\dots\dots \text{Equation – A.7}$$

Where,

$V_{PORE}$  is the pore volume in cc

$V_{REF}$  is the reference volume in cc

$V_{BR}$  is the volume of the removed Billets in cc

$P_{REFFULL}$  is the reference pressure for full cup measurement, psi

$P_{ZERO}$  is the zero pressure with the Helium Source valve closed, psi

$P_{CUPFULL}$  is the cup pressure with no billets removed, psi

$P_{REFREM}$  is the reference pressure with a billet removed, psi

$P_{CUPREM}$  is the cup pressure with a billet removed, psi

$P_{DV}$  is the pressure when the reference system is opened to the new dead volume,  
psi.

# *Appendix C*

## **GENERAL OBSERVATIONS**

## **APPENDIX C**

### **GENERAL OBSERVATIONS**

This appendix contains some basic remarks concerning the construction of the model and suggestions to improve the construction of such experimental set-up:

1. A new set of electrode was inserted at a distance of 1.5 cm from the well later on by making holes in the body of the model reservoir and copper rods were used as electrodes. These electrodes were exactly in the desired position and were in good contact with the media throughout the experiment, regardless of the position of the model.
2. The top plate was kept separate from the rest of the body of the model to facilitate any kind of change inside the model. The other sides were fixed to each other using screws and glue. The top plate was attached with rods and nuts to the bottom part. The top plate was broken while fixing it on the model. This was due to imbalanced forces applied through the 40 rods used. It was needed to fabricate another top plate before starting the experiment.

3. The model was heavy (150 kg) and could not be easily moved once filled. During injection of fluids and measurements, care was taken to avoid any kind of imbalance and tilting. Besides, the base of the model, also made of Plexiglas, was too weak to support the total weight. Any displacement of the model was done very carefully. A more robust construction is required in order to easily manipulate such a heavy construction.
4. An alternate and certainly better solution would have been to put the opening in the bottom plate and to incorporate hooks to allow transportation. While putting the model upside-down, the model fell and several cracks appeared on the body of the sector model. The last part of the experiment was conducted by keeping the model in a fixed position.
5. The holes drilled in the Teflon type plastic pipe, used as the well in the model reservoir, were small enough (0.4 mm) to prevent the glass beads (0.5-0.6 mm) from flowing out. So, there was no need to put any screen to the well.
6. At the sharp end of the model, the velocity of fluid was high due to the small size of the flow area. This caused some glass beads to be displaced from the compacted location and created bad contact of electrodes with the porous media.
7. Keeping the sector model in the reverse direction (the well at the bottom) was a better idea to increase pressure in the vicinity of the well and to have a compacted media close to the well. This arrangement allowed less permeability and higher connate water saturation and provided better measurement.

A correct positioning of the electrodes is a key factor for the interpretation of the measurements. The second set of electrodes, which was inserted once the model was closed, gave good measurements.

1. The acquisition system was originally designed for the monitoring of water saturation changes in an actual reservoir and was not optimum for measurements performed in an oil-bearing medium where the impedance of the medium can reach several  $M\Omega.m$ .
2. The acquisition system was powered by 220 volts supply line. The injected current was limited to 20 mA and the maximum voltage to 300 V; all measurements have been done at 10 Hz. At this frequency, the DC approximation is valid and polarization effects of electrodes are avoided. The shapes of the measured potential and injected current are displayed together with the corresponding values during measurement sequences. This feature allows one to detect any error during measurement.
3. Current was injected through the first electrode of the array (source electrode) with respect to a reference electrode and the potential distribution was measured using the other electrodes of the array with respect to another reference electrode.

## **NUMERICAL MODEL INPUTS**

## **APPENDIX D**

### **INPUT FILES FOR NUMERICAL MODEL**

Different input files were needed for to use the simulation model.. Some of the input files are included below. Contents in lines of Input Files:

Line 1: Name of the file

Line 2: skip

Line 3: Angles, Radiuses, and Elevation points for grids.

Line 4: Number of co-ordinates

Line-5: Values for radiuses (continues to other lines also).

Line 6: Z values (Continues to other lines also).

Line 7: Skip

Line 8: Position of reference electrode.

Line 9: Number of total electrode, number of current electrode

Line 10: Position of the electrodes (after C).

Line 11: Resistivities of the porous zones.

Line 12: Definition of zones with various resistivities.

Line 13: Name of the output file.

Input file for a reservoir model in a large area of interest
--

```

**VITA  
OF  
MUHAMMAD REAZ UDDIN CHOWDHURY**

*Addresses:*

*Saudi Arabia:*

KFUPM Box # 1182  
Dhahran 31261  
Ph: 03-860-5437

*Bangladesh*

126 New Paltan Lane  
Azimpur  
Dhaka-1205

*U.A.E.*

C/o, A. H. Chowdhury  
P.O. Box # 8437  
Musaffah, Abu Dhabi

Email: [g200427@kfupm.edu.sa](mailto:g200427@kfupm.edu.sa), [mdreaz@hotmail.com](mailto:mdreaz@hotmail.com)

---

*Date & Place of Birth:*

22<sup>nd</sup> November 1975, Dhaka, Bangladesh.

*Education:*

**Sept. 2000 – Dec. 2002:** M.S. in Petroleum Engineering, King Fahd University of Petroleum & Minerals, (KFUPM), Dhahran –31261, Saudi Arabia.

**Jun. 1994 –Sept. 1999:** B.Sc. in Chemical Engineering, Bangladesh University of Engineering & Technology (BUET), Dhaka –1000.

*Experiences:*

- Served as a Project Engineer in “Tetrahedron Inc. Bangladesh- An Arsenic Mitigation Project” from February 2000 to August 2000. The job involved working with water analysis and fieldwork with the installation and supervision of ‘Tetrahedron Arsenic Mitigation Filter’ as a team leader.
- Working as a Research Assistant in the Petroleum Engineering Department of King Fahd University of Petroleum & Minerals.

*Professional Memberships:*

American Institute of Chemical Engineers (AIChE), Saudi Arabia section and Society of Petroleum Engineers (SPE).
